### LECTURES ON FEVERS.

By ALFRED L. LOOMIS, M.D.,

PROFESSOR OF PATHOLOGY AND PRACTICAL MEDICINE IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.

(Phonographically reported for THE MEDICAL RECORD.)

#### LECTURE VII.

##### TYPHOID FEVER (CONTINUED).—TREATMENT.

GENTLEMEN: We have already considered the antipyretic power of cold applications in the treatment of typhoid fever, and I will now call your attention to the antipyretic power of the sulphate of quinine.

When quinine is employed as an antipyretic, it must be given in large doses; the administration of two grains every two hours, or a larger quantity administered in divided doses within a period of twenty-four hours, will not act as an antipyretic; but thirty or forty grains must be administered within a period of two hours.

If the stomach is irritable, and you fear that a large dose will produce vomiting, ten grains may be given every half hour until the desired quantity has been administered.

Usually from four to six hours after the antipyretic dose has been taken, the fall in temperature will begin, and in about twelve hours it will reach its minimum height; then it will remain stationary from twelve to twenty-four hours. After the temperature has once been reduced by the quinine, its administration may be discontinued until the temperature shall again rise to 105° F. As a rule, the temperature rarely ranges as high as before the quinine was administered.

This mode of administering quinine in antipyretic doses to fever patients rarely produces any symptoms of cinchonism, other than a transient deafness after the first dose. In a large number of cases the temperature can be kept below 103° F. by the sulphate of quinine; but in very severe cases it will be advisable, and sometimes it will be absolutely necessary, to employ not only the quinine, but at the same time the cold baths. My rule is, after I have reduced the temperature to 101° F., or 102° F., by a cold bath, to administer an antipyretic dose of quinine, and thus delay the recurring rise of temperature. While the cold bath more rapidly reduces temperature, the effect of the quinine is more lasting; consequently, by making use of both of these reliable antipyretics during the first two weeks, you will be able to control the temperature during that time. After this period it is not safe to resort to cold baths; but when the temperature rises above 103° F., occasionally you may use the cold pack in connection with antipyretic doses of quinine. If, during the third and fourth weeks, you fail to reduce the temperature by these means, administer during the twenty-four hours from ten to twenty grains of powdered digitalis—unless the pulse is very frequent and irregular—when its use is contraindicated. As an

antipyretic, digitalis should be administered only when quinine is given. It seems to increase the antipyretic power of the quinine, but has little or no power when administered alone.

The use of all these antipyretic remedies must be persisted in, until the desired end—the reduction of temperature—is accomplished; but the peculiarities of each patient must be studied, and these agents must be so administered as to suit each individual case.

You cannot trust to the judgment of nurses and attendants, but you must determine for yourself what are the requirements in each case.

The satisfactory results obtained by the systematic use of these remedies justifies their employment; but the exact rules which are to govern one in their use, as to manner and time, can only be determined by experience.

All careful observers are aware that great danger attends prolonged high temperature; but it is still an unsettled question whether this danger is due to parenchymatous changes in the different organs, which some claim are the result of the high temperature, or to disturbance of the nerve centres from the same cause. Whatever may be the final settlement of the question, the beneficial results which follow the antipyretic treatment of fevers are generally admitted; and my advice to each one of you is, at the onset of your professional career to make yourself perfectly familiar with the use of these most important and reliable antipyretics.

If you can keep the temperature of your patient at about 103° F. during the first two weeks of the fever, you have accomplished the *first* and perhaps the most important thing in the treatment of this disease.

Towards the end of the second, or during the third week, sometimes earlier, sometimes later, signs of failure of heart power begin to manifest themselves; the pulse becomes feeble and irregular; at times the surface is cool and moist; the patient complains of a sense of exhaustion, perhaps is unable to turn in bed; the tongue assumes a dry, brown appearance, and the necessity of supporting the patient becomes apparent. This will bring you to the *second* important question in the treatment of this fever, namely, *what means shall be employed to sustain heart power*, or, as it is sometimes said, the vital powers of the patient?

When a patient, during the second or third week of the disease, dies from capillary bronchitis, pulmonary oedema, or suddenly passes into a state of coma, failure of heart power is the real cause of death.

In those cases in which, during the early part of the fever, you have been compelled to resort to a vigorous antipyretic treatment, during the third week, although the temperature may not rise higher than 101° F., the pulse frequently becomes extremely feeble, and reaches 140 per minute, the first sound of the heart becomes inaudible, muscular tremors, dry tongue, and all the phenomena which indicate failure of vital power are present. Under such circumstances the use of stimulants seems to be urgently demanded.

There are a few simple rules which may guide you in the administration of stimulants in this fever.

*First*.—They should never be administered indiscriminately—that is, never give a patient stimulants simply because he has typhoid fever.

*Second.*—When there is reasonable doubt as to the propriety of giving or withholding stimulants, it is safer to withhold them, at least until the signs which indicate their use become more marked.

*Third.*—In every case, but especially when stimulants are not clearly indicated, watch carefully the effect of the first few doses. There are few whose experience in the treatment of typhoid fever is such as to enable them to positively determine, from the appearance of the patient, when the administration of stimulants should be commenced.

Should you commence the administration of stimulants, it is necessary to see your patient every two hours, and note carefully the effect produced. If you find the tongue becoming dry, the patient more restless, the delirium more active, the temperature ranging higher, and the pulse more and more rapid, you may be certain that stimulants are contraindicated. If, on the other hand, the pulse becomes fuller and more regular, if the first sound of the heart is more distinctly heard, or, if it has been absent, it has returned, if the restlessness and delirium is less marked, the tongue more moist, and the patient more intelligent, you may be certain that the time for the administration of stimulants has arrived. When you have commenced their use, it is of the greatest importance that you administer them at stated intervals, especially during the night.

In a severe case of typhoid fever, a free administration of stimulants, just at a critical period (which may not last more than twenty-four hours), will often be followed by a refreshing sleep, and your patient may rapidly pass from an apparently hopeless condition to one of convalescence.

The *third* important thing to be accomplished in the management of typhoid fever patients is the maintenance of nutrition. You must bear in mind that the primary and principal effects of the typhoid poison are manifested in the changes which take place in the lymphatics of the gastro-intestinal tract. Experience has taught us that the enfeeblement of the digestive and assimilative powers, due to these glandular changes, which are manifest from the very commencement of the fever, renders the digestion of solid food impossible, and for a long time it has been the rule of the profession to allow typhoid fever patients only liquid food.

There has been and still is great diversity of opinion in regard to the special articles of diet best suited to this class of patients. Most medical writers and practitioners claim that beef-tea is the proper diet for fever patients; consequently it is the rule to pour into these enfeebled stomachs a decoction of beef in such quantities as a healthy stomach could hardly tolerate, and which, in itself, has little or no nutritive element.

Others claim that gruels are far superior to animal broths, and advocate the feeding of fever patients with gruel made of barley and other farinaceous substances, to the exclusion of every other article of diet; yet gruels furnish few elements essential to the nourishment of a physical organization struggling against a subtle poison, and rapidly wasting with a burning fever, and starvation is the necessary result of a restriction to gruel diet.

There is no disease in which a waste of all the tissues of the body goes on so rapidly as in typhoid fever; and milk is an article of diet which furnishes the elements of nutrition necessary to repair this rapid waste, and there are not the objections to its use which there are against animal broths and gruels. Although there have been, and still are, in some quarters, strong

objections against its use as an article of diet in fevers, recently it has been regarded with more favor, and those who have had most extended opportunities for testing its nutritive qualities have come to regard it as the only article of diet required by fever patients. In it we not only find all the elements required for repairing the rapidly wasting tissues, but they are in a condition to be most readily assimilated by the enfeebled digestive apparatus.

In order to make the milk more digestible, it may be diluted with lime-water. The lime-water is an antiseptic, and allays irritability of the stomach and intestines. The quantity of milk is not limited; the patient may take all his stomach will digest—usually patients will take from four to six quarts in the twenty-four hours.

After the patient has passed into the fourth week of the disease, you may find it necessary to administer cream and the yolk of eggs in connection with the milk.

Having considered the three most important things to be accomplished in the management of typhoid fever, I now come to the treatment of the accidents of the disease.

*Diarrhœa.*—I have told you that diarrhœa is one of the common symptoms of this fever; but it is one of which medical writers have taken special notice, and for the relief of which different means have been employed.

Let us for a moment notice the chain of phenomena of which diarrhœa is a link. The poison which produces this fever unquestionably has a specific action upon the intestinal glands and lymphatics. It is here that we find the characteristic lesions of the disease, and it is scarcely questioned that the typhoid poison, to a great extent, gains entrance to the system through these glands and lymphatics, and here produces its primary irritation. Following the irritation and inflammation of the follicles, other portions of the mucous membrane become involved, and we have a catarrhal inflammation of the mucous membrane of the intestinal tract. The necessary consequence of this is a diarrhœal discharge. Is this diarrhœa to eliminate the fever poison? Certainly not. It is simply an indication that these intestinal changes are going on; it is not due to the elimination of the typhoid fever poison, but to the inflammation which the fever poison has excited in the intestinal glands, and the subsequent intestinal catarrh. When the diarrhœa is present in the earlier period of the disease, it is better to let it alone. The question may be asked, will it not exhaust the patient? During the earlier period of the fever (the first and second week) the danger is very slight. It has been proposed to treat this diarrhœa, which makes its appearance early in the disease, with alkalies, bismuth, pepsin, etc. It is claimed, if these remedies be administered, diarrhœa can be prevented, or, if it already exists, that it can be controlled. Theoretically, I see no reason for employing alkaline remedies, for the diarrhœal discharges are always strongly alkaline, and, from clinical observation, I am convinced that bismuth, pepsin, etc., have little or no effect either in controlling the diarrhœa or in preventing the intestinal changes which produce it. When diarrhœa commences late in the disease (during the latter part of the third, or during the fourth week of the fever), it is of a very different character from that which occurs during the first and second weeks. Ulceration of the intestinal glands, and perhaps sloughing, has been established, and, in addition to the extensive local changes, there is a septic element which enters into the causation of the diarrhœa at this

stage. Besides, the increased peristaltic action of the intestines, which attends the diarrhoea, favors an extension of the inflammatory processes to the peritoneum, especially that portion which covers the intestine, which corresponds to Peyer's patches. In view of these facts, the diarrhoea should be arrested or held in check. For the accomplishment of this, there is but one remedy which can be relied upon—that is opium. My experience is against the use of astringents. If opium will not arrest it, you may expect little aid from astringents combined with opium as they are usually administered.

The use of opium is objected to by some, who claim that it diminishes the power of the heart's action; but in this disease, when administered in small doses, it seems to me to increase rather than diminish the heart-power. It is acknowledged that opium, more than any other drug, arrests the peristaltic action of the intestines; and that is what we wish to accomplish, when diarrhoea is present during the third and fourth week of typhoid fever.

*Tympanitis.*—You will recollect that the tympanitis, which is sometimes so troublesome a symptom in typhoid fever, is due to gaseous distention of the intestines. Some assert that this gaseous accumulation is due to fermentative processes going on in the intestines; consequently, that the use of antiseptic remedies are indicated, such as muriatic acid, chlorate of potash, pepsin, etc. When this has proved a distressing symptom, I have usually found relief to be obtained by the application of turpentine stupes to the abdomen. Some claim that if turpentine be administered internally, from the beginning to the end of typhoid fever, that tympanitis and the intestinal changes which lead to it and to the diarrhoea are much less severe. I am confident that the turpentine treatment, as it is called, does not have the controlling influence over this fever which has been claimed for it; but I am also certain that it is our most reliable agent for the relief of the tympanitis.

*Intestinal Hemorrhage.*—Hemorrhage from the bowels in typhoid fever (as I have already stated) is a serious accident, and may cause death by producing a fatal exhaustion.

When it occurs early in the fever, usually it requires no treatment; but when it occurs during the third or fourth week, or after convalescence is apparently fully established, it must be arrested as promptly as possible.

The occurrence of severe intestinal hemorrhages may sometimes be prevented by keeping the patient in bed. A typhoid fever patient should not be allowed to get out of bed from the beginning of the attack until convalescence is fully established. Especially is this of importance if the case is a severe one, and attended by symptoms that indicate extensive intestinal lesions.

When hemorrhage from the intestines does occur during the third or fourth week of the fever, at once semi-narcotize your patient by the administration of opium in small doses at short intervals. Absolute rest of the body must be insisted on, the patient must not be turned on the side or moved in bed, and an ice-bag should be applied over the abdomen. I doubt if any good results can be accomplished by the use of astringents, either by enemata or by the mouth, as it is not known that they even reach the seat of the hemorrhage, although gallic acid and the persulphate of iron are usually recommended in cases of intestinal hemorrhage occurring in typhoid fever. If the hemorrhage is profuse, it may be necessary to keep your patient under the influence of the opium for a week or ten days.

*Peritonitis.*—When perforation of the intestine occurs, the case may be regarded as hopeless; death takes place usually within twenty-four hours; death occurs as the result of general peritonitis; no plan of treatment avails anything. If the peritonitis occurs without perforation, from the extension of the inflammatory process from the intestinal ulcers to the peritoneum, by bringing your patient rapidly into a state of semi-narcotism and holding him there for five or six days, you may prevent the extension of the peritonitis and save the life of your patient. Such a case you are to treat in every respect as one of localized peritonitis.

After recovery from an intestinal hemorrhage or a localized peritonitis in typhoid fever, be exceedingly careful about the administration of cathartics or enemata; either may jeopardize the life of your patient. The bowels will move spontaneously after a time, even though the use of opium be continued, and no harm will follow should two or three weeks pass without a movement from them.

When the stomach is irritable, the hypodermic injection of morphine is preferable to opium administered by the mouth. This is given to paralyze the peristaltic movement of the intestines.

*Bronchitis.*—I have already stated that catarrh of the larger bronchial tubes is present in all severe cases of typhoid fever. No special treatment is required for its management; but, if the bronchitis becomes capillary, great relief will be obtained from the application of dry cups to the chest and the internal administration of carbonate of ammonia. Vapor inhalations will also be found of service in severe cases.

*Pneumonia.*—The pneumonia which complicates typhoid fever in nearly every case is lobular in character. The signs which indicate its occurrence are sudden rise of temperature, increased frequency of respiration, and the physical signs of localized pulmonary consolidation; cough and expectoration are rarely present.

Its occurrence is always an indication that stimulants should be administered. If they are being administered, they should be increased in quantity. To prevent or relieve the hypostatic congestion of other portions of the lung, which frequently accompanies pneumonic development, the heart-power must be increased, and the position of the patient changed.

*Laryngitis.*—For the relief of the laryngitis which occasionally complicates typhoid fever, a small blister may be applied on either side below the angle of the jaw, and the whole neck enveloped in a poultice. If these measures fail, and suffocation appears imminent, tracheotomy should be resorted to without delay.

*Subacute gastric catarrh,* occurring as a complication during convalescence from the fever, can only be managed successfully by giving the stomach rest as far as possible, restricting the diet to a single tablespoonful of milk at a time, and applying hot fomentations over the epigastrium.

*Bed-sores.*—The severer forms of bed-sores are the most intractable complications we have to combat. Fortunately, the severer forms are much less frequently met with under the more recent plan of treatment; and, if they do occur, they are superficial and limited to small spots. Scrupulous cleanliness is one of the principal means for preventing their development. So long as there are no erosions, the parts should be frequently bathed in spirits of camphor, and the points of attack should be relieved from all pressure. If the sores penetrate the integument, they should be frequently washed with a weak solution of carbolic acid, and afterwards covered with lint covered with vasaline.

The most unfavorable cases are those in which the point of pressure caused by the weight of the body becomes gangrenous. In such cases, by some a continuous warm bath is recommended. As soon as sloughing takes place, and the parts separate, they should be dressed with lint saturated with balsam of Peru and carbolic acid.

As has been already stated, diarrhoea is usually present in the early period of this fever; but sometimes there is constipation. The question arises, is the administration of cathartics ever admissible in typhoid fever? If so, what cathartic shall be employed? There is great diversity of opinion upon these points. One recommends the administration of rhubarb, another advises alkaline cathartics, and another would give calomel.

I shall consider these at my next lecture, in connection with the management of convalescence and the sequelae of this fever.

## Original Communications.

### NEW MODIFICATIONS OF THE OPHTHALMOSCOPIC MIRROR.

By EDWARD G. LORING, M.D.,

NEW YORK.

DR. O. F. WADSWORTH, of Boston, has recently made an ingenious and what promises to be a useful addition to my ophthalmoscope. This consists of an additional mirror, designed particularly for the use of the upright image and the determination of the errors of retraction. The mirror is circular in shape, and of the same focus as that now ordinarily used. The peculiarity of the mirror is that it is only fifteen millimetres in diameter. The small diameter of the mirror permits it to be set at an angle of twenty degrees, and yet allows the hole in the mirror to be brought close to the glass in the disk. The mirror rotates from right to left, so that either eye can be examined. The disadvantages of this mirror are, that it is so small that sufficient light is not obtained to make an examination by the inverted method, thus necessitating an alternate substitution of two mirrors. To avoid this necessity, I have contrived the following modifications of the ordinary mirror, suggested by Dr. Wadsworth's idea:

The general shape of the mirror is kept as it now is, except that a segment is cut from one side, a straight line having been drawn in a vertical direction about half-way between the centre of the hole and the edge of the mirror. The mirror is then swung on two pins in a vertical direction. When an inclination is needed, the mirror is tilted down into the case, at the side which has been cut away; and, as only ten degrees of pitch within the case is needed, the present case is deep enough. When needed for the inverted image, the mirror can be folded back, or indeed used just as it is. This mirror rotates from right to left. It gives abundant light for either method of examination, and can, if thought advisable, be protected by a case similar to that of Jaeger's mirror.

This modification has been rendered still more simple by cutting off both sides of the present mirror, making in fact a narrow parallelogram sixteen millimetres in width, instead of a circular mirror. This tilts both ways in the case, and does not have to be rotated, and can be used perfectly well for either up-

right or inverted image. If more light should be needed, it can be obtained by having the segments which have been removed, restored. The mirror would then consist of three parts—a central portion which swings on pivots, and two side portions which remain stationary. Still a further modification towards the same end, and one which is more elegant but more expensive, is to have a small central mirror swung on pivots, surrounded by a concentric stationary mirror. These mirrors can be fitted to any ophthalmoscope. By such an arrangement we do away, in a great degree, with the astigmatism which is produced when strong glasses are used, and when the mirror lies in a plane parallel to that of the correcting glass, as is the case with the ophthalmoscopes now in common use.

These mirrors can be had of Mr. Hunter, optician, 1132 Broadway.

### THE STATE OF THE EYELIDS AFTER DEATH—OPEN OR SHUT?

By T. CLARKE MILLER, M.D.,

MASSILLON, OHIO.

In order at once to relieve myself from the burden of a sensational heading, I will explain that my object in this writing is to inquire what importance, if any, is to be attached to the state of the eyelids (open or shut) after death.

In a criminal trial at the present session of the Court of Common Pleas of Stark County, Ohio, at Canton, the county-seat, in the case entitled "The State of Ohio *v.* R—," the State sought to attach importance to the fact in evidence that the eyes of the deceased were *closed* when the body was first seen by witnesses after the tragedy. A part of the theory of the prosecution seems to be that the mortal wound (pistol-shot) was inflicted while the victim was *asleep*; that, as appears in evidence, the wound was from its nature necessarily *immediately fatal*; and that the eye being *found closed*, was evidence that the mortal wound was received *during sleep*.

If this could be made to appear, of course the plea of self-defence must fall to the ground.

It is not my desire to discuss the merits of the case or the value of the evidence, whether as to fact or expert; but I think I may ask the indulgence of your readers while we inquire:

1. Whether the fact of the eyes being found *closed* after death is of any value as evidence that the *wound was inflicted and death occurred during sleep*?
2. What determines the *closure* or otherwise of the lids after death?
3. Is the state of the eyelids (open or shut) of *any medico-legal* importance?

1. The writer has seen men shot dead in the army, in battle, during the late war, and has seen after their death that the eyelids were closed; it is not asserted that this was *always* the case—this is not necessary; but it certainly was *sometimes* the case. Having had considerable opportunity for observation in civil life, I do not hesitate to say that in very many cases of "sudden" or "instant" death, whether from violence of a criminal or accidental nature, or from disease, the eyelids will be *closed* after death. In answer then to the first question I feel safe in saying, "that the fact of the eyes being found closed after death is *not* of any value as evidence that the wound was inflicted or that death occurred during sleep," even though it be in evidence that the wound was necessarily *instantly* fatal.

2. In the class of cases already spoken of, *i. e.*, sud-

den or instantaneous deaths, we have already seen that the eyelids are *very frequently* partially or entirely closed (oftener than otherwise) after death; and is not the explanation of this to be sought in the same laws that determine the position of other parts of the body?

If a person receives an instantly fatal hurt the muscles at once lose their tone and contractile power or quality, and the limbs fall into such positions as *gravitation* determines, modified by the surroundings, and, if the body be not disturbed, cadaveric rigidity coming on fixes the body for a time in that position. If the head is in such a position as to *favor*, the lower jaw drops; otherwise, of course, it does *not* drop. The eyelids obey the same law; if the body falls, or is immediately placed on the back, with the head a little elevated, *gravitation favors the descent of the upper lid over the eyeball*; there is ordinarily nothing to *hinder*, consequently the eyelids are *closed*.

On the other hand, if the body falls or is placed on the *face* or on the *back*, with the head *low* or *thrown back*, the eyelids will be found *open* to a greater or less extent. Even in death by hanging, which is in many instances not strictly instantaneous, and in which the constriction of the neck is thought to favor a protrusion, in a greater or less degree, of the ball, the eyelids are *very often* found closed, if in fact this is not *generally* true where the body has remained suspended for some time.

But what ordinary influences, aside from or in defiance of gravitation, may determine the *openness* of the lids after death?

At the approach of death from tedious and exhausting sickness the *senses* of the sufferer become gradually and progressively *blunted*; reflex phenomena cease to manifest themselves; whether the chill finger has touched the nervous *centre* or the peripheral expansion, matters not, the muscles cease to obey even before the will has ceased to command. The eyeball now bears exposure to the air, and the irritation is not responded to by a *reflex* wink; no discomfort is felt, and the lid does not sweep the ball by a *voluntary* effort; the eye becomes "glazed," the secretion is *dried up* so that the lid does not slide over it of its own weight; the heart stops, and the rigor of death *fixes* the victim in the expression of limb and feature with which the monstrous victor leaves him.

The second question may then be answered: gravitation and the state of the lubricating secretions of the eyeball are the considerations which determine the closure or otherwise of the lids after death."

3. The condition of the eyelids after death, taken in connection with the position of other parts of the body, all of which might be included under the name of *cadaveric expression*, will help materially in determining whether or not the body has been moved from the position taken at death or at the time when the muscles began to be rigid.

This part of the subject would bear, and deserves, a degree of elaboration which I will not attempt at present; and will only further say, that it seems evident that the state of the eyelids (open or shut) is or may be of considerable medico-legal value.

PREVENTION OF FIRES IN PUBLIC BUILDINGS.—At a recent conference of the heads of departments in this city it was shown that the responsibility of preventing fires in public buildings rested entirely upon the Department of Public Buildings. That this was not definitely understood before proves how derelict that department has hitherto been in the legitimate discharge of its duties.

## Progress of Medical Science.

DISEASE OF THE MEDULLA OF THE BONES IN PERNICIOUS ANEMIA.—Prof. Cohnheim, of Breslau, reports the case of a man of thirty-five, who died in the hospital at that place of progressive pernicious anemia, the disease having presented all its usual features. It was found at the autopsy, among other things, that the medulla of all the bones was intensely red. It contained no fat-cells, but instead of them the so-called cells of the medulla, with colorless and colored corpuscles, comprising the ordinary red blood corpuscles, and also, in great excess, red nucleated corpuscles of various sizes. Nuclei and corpuscles were alike colored, and they were remarkable for their great elasticity and ductility. Similar cells were also found in the blood, and in the liver and spleen. Cohnheim regards this condition of the medulla as closely related to the fatality of the disease, indicating a retrogression to an embryonic state of the medulla, or a formation of the cells mentioned at the expense of the healthy blood corpuscles.—*Virchow's Archiv*, 68, II., 1876.

A NEW EXPLANATION OF BLUE PUS.—Dr. Girard supports the views of Ferdoz as to the existence of a blue and a yellow coloring matter in pus—pyocyanin and pyoxanthose—and he declares that the bluish tint is due to an excess of the former. It was observed in the shape of hexagonal crystalline tables, blue needles, groups of crystals, or occasionally dark blue octahedra. Pyoxanthose was also present, generally in a granular crystalline form. The excess of one or the other coloring matter determined the tint of the pus. This is opposed to Lücke's view that the blue color is due to great quantities of organisms resembling vibrios.—*Chir. Centr.-Bl.*, II., 50, 1875; *Schmidt's Jahrb.*, 1876, Bd. 171, No. 9.

DETERMINATION OF MERCURY IN THE MILK OF A WOMAN DURING TREATMENT BY INUNCTION.—Dr. Edward Klink concludes that the failure to find mercury in the milk of a nursing woman who is treated by inunction, is because the quantity of milk examined has been too small. He reports the case of a woman suffering from various syphilitic manifestations, who had twenty-five inunctions of thirty grains of mercurial ointment daily. The child had broad, ulcerated condylomata and glandular swellings. It was given three baths with corrosive sublimate, which were discontinued because they produced diarrhoea. It soon recovered from the syphilis. K. therefore considered that the cause of the child's improvement was to be found in the mercury, supposably contained in the mother's milk. The milk was accordingly submitted to chemical examination in Prof. Tudakowski's laboratory, at Warsaw, the quantity amounting to rather over eleven and a half ounces, taken on fifteen days subsequently to the thirteenth inunction. The presence of mercury was clearly proved.—*Jahrschr. f. Dermatol. u. Syph.*, III., 2, p. 207, 1876; *Schmidt's Jahrb.*, 1876, Bd. 171, No. 9.

CROWDING OF PUBLIC SCHOOLS.—The public schools in this city are very much overcrowded, and the water-closets of many of them are in a very filthy condition. We should like to know who are charged with the responsibility of inspecting them?

# THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, January 6, 1877.

## ADULTERATION OF MILK.

THE recent conviction of Shrumph for selling adulterated milk has been the occasion of much congratulatory comment by the daily press. The case being singled out by a powerful association of milk-dealers to prove the legality of the test used by the Health Board, more than an ordinary interest was excited in the proceedings.

Although the result obtained has been everything to be desired from a sanitary point of view, and although there is a general belief that the verdict of the jury was just, it is, scientifically speaking, at least, a matter of regret that the triumph of the Board was not more complete. Considering the ability of the President of the Board as a practical chemist, and his reputation as an expert, we are not a little surprised to find him basing the strongest arguments of the prosecution upon the value of the lactometer as a test for milk adulteration. The instrument used by the Board was graduated from 1.029, and for convenience of use this point on the scale was marked at 100°, which was considered to be the lowest standard consistent with good milk. This was well enough as far as it went, but there does not seem to be any reason why it should not have been admitted that other means of examination were frequently necessary. There is no doubt that the lactometer is the test for the specific gravity of milk; that water added to pure milk will lower its specific gravity; that milk thus diluted will show by analysis an equivalent excess of water; and that the "commercial milk" as sold in New York, is, as a rule, always above 1.029°, or the equivalent standard of the Health Board 100°. The arguments upon which these statements were made were sufficiently convincing, neither could it be denied that the milk sold by the defendant was not much below the usual lactometric standard.

It is not surprising, under the circumstances, that the defence should strive to prove that the lactometer

was not a reliable instrument, and was far inferior to the usual analytical processes. For the accomplishment of such a purpose there was a fine opportunity for the exercise of legal tact and the judicious management of expert testimony. Prof. Doremus and sons, appearing for the defendant, showed without difficulty, first, that the Health Board lactometers did not always correspond; secondly, that the standard adopted by the Board was not absolutely correct, pure milk ranging frequently as low as 92° at ordinary temperature; and thirdly, that cream will of itself lower the specific gravity, the richer varieties of milk being sometimes below the Health Board standard of 100°. Thus much being proven, the conclusion which forced itself for consideration was that the defendant could not be convicted of adulteration on the evidence of the lactometer alone. So skilfully was this point presented to the jury, that, had not the Court ruled that the defendant and not the lactometer was on trial, the case might have assumed an altogether different aspect.

In reviewing the testimony in this case, there are several questions of scientific interest which present themselves, in regard to the best means to be used for the detection of adulteration in milk. Lactometry is perhaps the simplest method under ordinary circumstances, but not trustworthy under extraordinary circumstances. We may accept the standard of the Health Board, and say that for practical purposes it is just; but, considering the wide range of specific gravity (92° to 108°) in pure milk, we are not warranted, scientifically speaking, in being too positive whether a certain specimen contains any extra water or not. In fact, the very awkward admission has to be made that the lactometer can sometimes imitate his Satanic Majesty by ruling both ways at once. For instance, a comparative low specific gravity may show either that the milk is very rich with cream or very poor by adulteration with water. Although it is not likely that dealers will prefer to adulterate with cream, unless, perhaps, when water is very scarce, it is still a fact that milk when fresh has a lower specific gravity than after the cream is skimmed from it.

In view of these facts, we are convinced that the lactometer has not only been dignified with an importance which it does not really deserve, but the almost absolute reliance placed upon it by the Board will, we fear, encourage rather than prevent fraud. If the milk-dealers are satisfied that the lactometer will be the only test for the purity of their milk, it will be policy for them to come as near the Health Board standard as possible. If cream keeps down the specific gravity the milk can be skimmed, and then if the "skimmed milk" marks too high a degree on the lactometer, the requisite amount of water can be added. Although this repeated use of the instrument may give the dealer some trouble at first, a little practice will soon enable him to decide exactly how much water is

necessary to make up for the absence of the cream. When we narrow the test down to the question of specific gravity alone, this is the way that the milkmen will probably answer it for us.

We are informed that no milkman is prosecuted unless his milk marks below 89°, and then a chemical analysis is made. No one can doubt that this standard is low enough to be suspicious, and that an analysis is eminently proper. But we do not see why it should not be proper in all other suspicious cases to use the same extra methods of proving adulteration.

Of course it is quite necessary to have some ready means of detecting adulteration, and more is the pity that the lactometer will not answer this purpose.

It is somewhat strange that the pocket microscope has not been thought of in this connection, a little practice in the use of which would enable any inspector to decide concerning the quality of the milk with a good deal of accuracy.

But, under the best possible chances of conviction of venders of adulterated milk, the Health Board have not yet reached the root of the difficulty. That the milk is adulterated before it gets into the hands of the small dealers, there is no question. In fact, this was so far admitted in this case that the Court charged the jury accordingly. The prevention of this state of affairs by the inspection of milk on its arrival at the depot is so easy, that it is hardly possible to believe that it was ever neglected.

#### DISSEMINATION OF DISEASES AT FUNERALS.

THERE are not wanting cases either in this country or Europe, to prove the danger of disseminating contagious diseases at funerals. Not long since the Suffolk District Medical Society made some inquiries in reference to this question of dissemination in connection with patients dying of diphtheria, and elicited some very interesting and suggestive facts. The result was the passage of a recommendation, to the effect that funerals of persons who had died of that disease should be private. We are pleased to notice that the Health Board of this city have issued a circular not only advising against public or church funerals of persons dying of diphtheria, but of scarlet fever, measles, and whooping-cough. There does not seem to be any good reason why our health authorities should not only actually forbid such funerals to be held in such places, but that the family of the deceased should be compelled to publish, with the announcement of the death, the particular contagious disease of which the patient had died, so that there should be the least possible danger with strictly private funerals. We have in mind a whole family of children which was sacrificed to scarlet fever by a neglect of this precaution, besides many scattered cases. Such, however, are so much more the rule than the exception, that it becomes almost criminal not to give a suitable warn-

ing in advance. In this connection it would be well to consider the possibility of restricting the transportation of the bodies of children dying of these diseases to hearses, rather than permitting the use of carriages for that purpose.

## Reviews and Notices of Books.

CONTRIBUTIONS TO REPARATIVE SURGERY. By GURDON BUCK, M.D., Surgeon to the New York and St. Luke's Hospitals. D. Appleton & Co. 1876.

THIS little volume of 237 pages is a record of the author's personal experience in a branch of surgery to which he has devoted himself with extraordinary skill and energy for some years past. The twenty-nine cases, whose histories are here recorded, do not cover the entire ground of reparative surgery; indeed, they may, in a measure, be regarded as unique cases, though they serve well to illustrate the principles which the author advocates in his treatment. To every practical surgeon the results speak for themselves; and as two or more excellent woodcuts accompany each case, showing the condition of the deformity before the operation and the final result, the reader can determine for himself the amount of success that was achieved.

Most of the cuts were executed by Froning, of Vienna, from photographs, and they are certainly very well done. Duplicates of the original photographs have been deposited in the Pathological Museum of the New York Hospital and in the Army Medical Museum, where they may be referred to. Some short but excellent chapters are devoted to general subjects, such as the transplantation of skin; the methods of transferring it; the treatment of raw surfaces left to heal by granulations; sutures, and their management; and methods of operation. The surgeon will find these chapters well worthy his attention, as they abound in excellent points that will prove valuable, especially in difficult cases. The rules for using the pin suture and the pin conductor may in many cases greatly aid the surgeon. The author has evidently aimed at great accuracy of description and the most copious illustration; his style is brief and succinct, and yet easy and pleasant. The book may be regarded as an important contribution to surgical literature, and a monument to the originality, skill, untiring perseverance, and faithful labor of its author.

THE CLIMATE OF JAMAICA, W. I. By JAMES CECIL PHILLIPPO, M.D., L.R.C.S. (Edin.), Member of the Medico-Chirurgical Society of Edinburgh. London: J. & A. Churchill, New Burlington St., 1876.

THIS interesting and valuable brochure of some 80 pages 12mo, includes the following table of contents: The Voyage to Jamaica, Kingston, and the Lowlands; From Kingston to the Mountains; The Climate of Jamaica; Tubercular Disease; The Diseases of Jamaica; The Mineral Springs of Jamaica. All these subjects are well treated, and it will pay the *invalids of our country* to read them, especially the health-seeker who expects to visit Florida or Mexico, or the Pacific Slope of the United States, etc. From our experience we would say, study the "New and Varied Excursion to the Tropics, for Invalids or Tourists," as published by Messrs. Alexandre & Fry, of Broadway, New York; but *do not omit to visit Jamaica* from some convenient port

made accessible by such a line. The truth is, that if our invalids, of whom alone one hundred thousand, not less, visit Florida every season, could only use a bridge to Jamaica, the Governor-General of the British West Indies and other influential parties there would subsidize a connection with the New York, Havana, and Mexican Mail Steamship Line. The passenger is not the freight line, and it is that connection which is to be supported until fairly started. We would recommend to Dr. Phillippo to get more information as to the various steamship and railway lines of the United States, and to consult the letters of our distinguished countryman, E. R. Peaslee, M.D., etc., published in the spring of 1876 in the *MEDICAL RECORD*, Nos. 285, 286, 287. These, with the circular of Dr. Grant's Sanatorium, or Home for Invalids at Cairo, Egypt, will give some valuable hints, both to the profession as well as to the laity. The climatologist knows the objections to Nice and Mentone, Algiers, Cairo, Egypt, Florida, City of Mexico, Cuba, and all else. We also know, for a winter resort for convalescents, the importance of the easy accessible highlands in the tropics. These are to be found in Jamaica. If the island government could furnish the bridge of *passenger steamers*, how many would cross it! The tourists of the North Atlantic steamers in summer, would only be equalled by such a line *merely for the voyage*, if the accommodations were as good. The wants of the island are first in a comfortable passenger vessel, and second, in a good hotel. Both of these the learned doctor should state how best they are to be provided for.

The climate, or rather *varied climates*, with the choicest fruits, and fine roads, are unequalled in any of the many climates we have visited. If the annexation of St. Domingo would make a *free Cuba*, what would not the reciprocity treaty, with the excellence of all that is connected with Jamaica, not do for *our health*. The description as you ascend with the learned doctor the Blue Ridge Mountains; the song of the birds; the beauty of the flowers; the cascades and creepers; varied foliage; large clumps of bamboos, like huge Prince of Wales' feathers; the early-morning effects of the flowers of logwood and ebony, which exhale a delicious odor; and all that feeling of exhilaration, lightness, and elasticity—all to mind our more than one visit. The "Open-Air Treatment of Consumption" (see Dr. Blake in *British Medical Journal* of June, 1875, or *Pacific Medical Journal*, 1850), can, in Jamaica, be always enjoyed. That the doctor dwells on and justly, as well as the *variety of climates* of the island. The highlands of our noble Hudson are compared at Cornwall-on-the-Hudson to the same climate in the mountains of Jamaica. The meteorological tables speak volumes, especially as to the *mean degree of humidity*. These tables are worth the volume in cost for the shelves of a medical library. The effect of the mountain climate on children, and the prolongation of life are well illustrated. Drs. Parkes and Bennet, Sir James Clark, Wern, Jourdanet, and many others, are well and justly commented on for their works on climatology; but the doctor's concluding paragraph is worthy of all praise, and we cannot but hope that he may favor his nearer neighbors and many friends by an *American edition enlarged*, for he has plenty of material. We will remember his quotation from Anthony Trollope, that he could not "imagine no more healthy climate in the world than that of the mountains around Newcastle, and all that he says of a state of bliss—as it were in a second Eden—a military paradise, in which war is spoken of, and dinners and dancing abound."

DOWELL ON YELLOW FEVER AND MALARIAL DISEASES: Embracing a History of the Epidemics of Yellow Fever in Texas; New Views on its Propagation and Control, Diagnosis and Treatment. By GREENSVILLE DOWELL, M.D., Professor of Surgery in Texas Medical College; Member of American Medical Association; Surgeon to the Medical College Hospital, etc., etc. Philadelphia: Medical Publication Office, 115 South Seventh street. 1876.

DR. DOWELL believes that he can speak with authority concerning yellow fever, from the fact that he has treated over 2,000 cases in hospitals and private practice. After the introduction the author at once gives an account of the symptoms of yellow fever, of which he believes there are three varieties: 1. Malarial fever, usually called malignant, congestive, or bilious, but which is not contagious or transportable, only in persons after infection; does not terminate in pure black vomit, etc. 2. Hepatitis acuta, the yellow fever of all climates; jaundice with or produced by inflammation of liver, spleen, and bowels. What the author means by inflammation of the bowels we are not able to say. 3. Infectious yellow fever; no one has a second attack of this, while they may have either of the other forms. It came from Africa to America, and is an eruptive or exanthematous fever, infectious or contagious from persons and clothes under certain circumstances not yet well known. The fomites cannot live in a temperature above 212° F. nor below 32° F. The cause is not carried in the air to any great extent. Every person is liable to have it, unless protected by a previous attack. Exclusion by quarantine, the author believes to be impossible. Unassisted or not treated, about seventy-five per centum die, while with proper treatment and nursing only about five per cent. of the cases prove fatal. Prophylactic remedies have not been successful, but much can be done in the way of prevention by the adoption of proper sanitary measures. To successful treatment, subordination of the nurse to the doctor is regarded as an absolute necessity. The history of the symptoms of the disease, treatment, etc., is followed by a chapter on quarantine, and then come "illustrative reports," which make up quite a share of the book. These reports are from twenty-five physicians who have had personal experience in connection with this affection. These are supplemented by the author's own experience, which has extended over a period of more than twenty-five years, and with it are incorporated several pages of statistics. The pathology and treatment of dengue is then taken up, and from this the author passes to the consideration of malarial fevers. The book is concluded by a few pages on diarrhœa hemorrhagica, or bloody flux. A chart is attached showing the elevation above sea-level of localities in which yellow fever has appeared since 1668. As a frontispiece we have four chromos from Blair. So much, as a general outline, of the contents of this monograph. As a general criticism, we bring forward the statement that there is an air of looseness, not to say positive blunders, hanging about the book from beginning to end. To particularize, we find at the commencement of the book the announcement, that the black vomit of yellow fever and the pigment of the eye are identical; in the middle portion, the prescriptions have been printed with the symbol for the fluid drachm substituted for that of the fluid ounce; and in the latter portion we find such unsatisfactory expressions as detecting hypertrophy of the spleen by "pressure;" "salivation by iodine while the patient was taking mercury;" "absence of the spleen with rupture into the stomach, permanent hypertrophy of the spleen and recovery of the

patient;" "curing hicough of eight days' duration by salivating the patient, thus breaking up the adhesions which had formed between the spleen and diaphragm;" "found at post-mortem the peritoneum highly inflamed and the colon contracted" (in diarrhoea hemorrhagica), etc., etc.

In the Mississippi and Brazos bottoms, the author claims, inflammation of the spleen is of common occurrence; so much so, that scarcely any one lives there from three to five years without having an attack. He also states that in all the cases of typhoid fever, in which he has made autopsies, he has found the spleen enlarged and "rather indurated," even in a child two years old. It is hardly possible for a man who has had twenty-five years' experience in the management of any disease to write concerning it without incorporating in his writings some valuable items, and so it is with regard to this author. But how much more valuable the book should have been!

**THE THIRTY-THIRD ANNUAL REPORT OF THE MANAGERS OF THE STATE LUNATIC ASYLUM, UTICA, N. Y., for the year 1875.** Albany: Weed, Parsons & Co., Printers, 1876.

The Report is presented in its usual form (Senate Doc. No. 17), and includes that of the Managers, the Treasurer, and the Superintendent.

In the Superintendent's report considerable space is given to the history of cases with the autopsies and microscopical examination of the brain. It is probably a legitimate inference that the microscopical work was largely if not entirely performed by the special pathologist of the Institution, and yet nowhere in the report has that fact been directly or indirectly acknowledged. If the observations were made by the Superintendent, it would have been policy for him to have held the special pathologist responsible by a graceful acknowledgment, rather than subject himself to the humiliation of presenting such a loop-holed report. As it is, the Superintendent must be held responsible for the value of the observations made upon the cases reported, and all that can be said is that they are only moderately good. There is a promiscuous mingling of gross and microscopical appearances; there is a looseness of statement regarding the changes present in the heart, lungs, liver, kidneys, and other organs that is inexcusable, coming as it does from one who has been placed high among specialists; and there is a familiarity in the use of the word "congestion" that savors more of some dark chamber of which but little more is known than the external appearance of the entrance, than it does of a thorough and scientific understanding. It is to be hoped that the next report will wear the impress of a more thorough scientific investigation; and though no more than three or four cases should be reported, that they will be found to be complete when viewed in the light of all the means afforded the modern investigator.

**A CENTURY OF AMERICAN MEDICINE, 1776-1876.** 12mo. pp. 366. Philadelphia: H. C. Lea, 1876.

This little volume comprises a republication of papers in the American Journal of Medical Sciences, by Drs. Edward H. Clarke and Henry J. Bigelow, of Boston; S. D. Gross, of Philadelphia; T. Gaillard Thomas, of New York; and J. S. Billings, of Washington, D. C. Taken as a whole it presents a very complete and connected review of the progress of medicine during the past century.

"**THE INEBRIATES' HOME FOR KINGS COUNTY.**" Incorporated 1866. Fort Hamilton, New York. Rev. J. WILLET, Superintendent.

We have received the circular and the "Living Wit-

nesses" from the Institution established for the treatment and reformation of Inebriates. We are happy to learn that in the Home so many of this poor unfortunate class of persons have been received, and apparently successfully treated. It is claimed that this has certain advantages over other kindred institutions in the way of hospital treatment, classification of patients, and in system and discipline.

**A COURSE OF ELEMENTARY PRACTICAL PHYSIOLOGY.** By M. FOSTER, M.D., F.R.S. Macmillan & Co., London, 1876; pp. 224.

This volume comprises twenty-eight lessons in demonstrative physiology, followed by an appendix upon the use of the microscope. The book commences with directions for the proper dissection of a rabbit or a dog, with methods for preserving their different organs and tissues for later studies. Lessons II. and III. are devoted to demonstrations of the morphology and physical properties of the blood, and of the phenomena which accompany coagulation. Lesson IV. considers cartilage, bone, and teeth; and Lesson V., connective tissue, fibres, etc. After chapters relate to the general properties of nervous tissue, to the structure and action of the heart, to the structure of the lung and the mechanics of respiration, the physiology of the skin and of the other organs of special sense, etc. As practical physiology cannot be studied without the aid of physiology, ample directions are given concerning the use of the microscope, the manipulation of tissues, and the cutting, staining, and preservation of the sections.

This work will prove of great value to the teacher of physiology as an aid to the preparation of an eminently practical course of lectures and demonstrations of elementary experimental physiology. Its chief utility, however, will be to the intelligent student, who, armed with a dissecting-case, a microscope, and the book, will be enabled to pass his summer vacation in a manner at once interesting and profitable.

**STUDIES, CHIEFLY CLINICAL, ON THE NON-EMETIC USE OF IPECACUANHA:** With a Contribution to the Therapeutics of Cholera. By ALFRED A. WOODHULL, M.D., Assistant-surgeon and Brevet Lieut.-Col. U. S. Army. Philadelphia: J. B. Lippincott & Co. 1876.

The author of this book has a theory which maintains that ipecacuanha is a stimulant to the sympathetic nervous system, hence its beneficial effects in the treatment of dysentery, acute and chronic, of some of the choleraic forms of intestinal disease, cholera morbus and cholera infantum, of nervous vomitings, of passive hemorrhages, and of intermittent fever. The efficient pathological cause in these diseases is believed to be "loss of nervous control." Put in the form of a syllogism the author's claim stands as follows:

The efficient pathological cause in certain diseases is deficiency of sympathetic nerve influence.

Ipecacuanha stimulates the sympathetic nervous system.

Therefore, those diseases which have for their cause loss of nervous control, or deficiency of sympathetic nerve force, can be cured by ipecac.

In the first place, the author admits (p. 86) that little or nothing is known of the nature of the nervous force; that he is not required to explain its exact mode of operation; and that "by *imagining* the nervous element in a state of unstable equilibrium, whose disturbance constitutes many forms of disease, we are materially aided in the comprehension of some diseases, and of the action of some remedies."

He further admits that vomiting may be the result of either irritation or depression of the nervous sys-

tem, and claims that ipecac is, from its peculiar effect upon the nervous system, especially the sympathetic, adapted to the relief of vomiting, because when it produces emesis, it is a tonic emesis.

Now, out of all this the author has attempted to bring his major and minor premises and draw a conclusion, and it is not absolutely certain but what he has succeeded, thus showing himself to be a most ingenious writer. He claims, however, to prove his propositions by the recital of clinical cases; but the major premise in his argument, according to his own citation, is but little more than an assumption, and we need not, therefore, pursue the phantom farther.

In the cases reported by the author, the drug apparently produced good results. To dysenteric patients the ipecac was administered in ten or twenty grain doses, in pill or suspended in a very small quantity of water; was preceded by about fifteen minutes with ten or fifteen drops of laudanum; and followed, after about the same length of time, by a mustard paste or tincture of iodine over the epigastrium. In cases of intermittent fever the remedy is more commonly given in doses of one grain, three times a day. A purely speculative chapter is given on the effect of ipecac in the treatment of cholera, and need not be noticed farther. In a closing chapter the author hedges with all the skill of a modern politician in answering the possible objection to the acceptance of his theory.

**A PRACTICAL TREATISE ON MATERIA MEDICA AND THERAPEUTICS.** By ROBERTS BARTHOLOW, M.A., M.D., Prof. of the Theory and Practice of Medicine, etc., etc. New York: D. Appleton & Co., 1876.

DR. BARTHOLOW has done much original work, and has given the profession several small books upon materia medica and allied topics, so that naturally his experience as a book-maker is somewhat extended, and the volume before us bears evidence of much thought, is well written, and also clear and attractive.

The author classifies his subject as follows: Part I. Modes in which medicines are introduced into the organism. In this chapter he considers the epidermic, epidermic, and endermic administration of remedies. Part II. Those agents used to promote constructive or destructive metamorphosis, those to modify the functions of the nervous system, and finally those to cause somævacuation from the body. Part III. is devoted to the discussion of the topical remedies.

In looking over the volume we are interested in the decided opinions of the author in regard to certain remedies—opinions which are somewhat in opposition to the views of other well-known authorities. On page 169 he expresses himself strongly in favor of iodide of potassium in the later stages of syphilis, in preference to the mercurial iodides. This opinion, we believe, is not held by the more advanced syphilographers, among them Drs. Sturgis, Piffard, and Keyes. We do not agree with him in regard to the value of injections of iodine in goitre where the author has obtained such good results, nor in hypertrophied tonsils. In the latter case tonsillotomy is far preferable to the plan he recommends, and we think more effective and attended with less danger.

His chapters which deal with agents that modify the functions of the nervous system, are perhaps the best ones of the book, and here we see the fruits of experience and study. We must, however, differ from him in some of his views in regard to medical electricity. We can never believe "that electro-physiology has not contributed very greatly to serve as a foundation for electro-therapeutics." We must protest against this statement, for we firmly believe that the only way in which electricity can be beneficially and

scientifically employed is with a thorough comprehension of the ground work of electro-physiology; otherwise we play the rôle of empirics.

We think the author lays too much stress upon phosphide of zinc, a remedy with few virtues. He, however, does discuss several drugs that have hitherto been little known, but are very valuable medicinal agents. One of these is hydrastin, which is an excellent injection in gonorrhœa. Very practical and sensible articles upon mineral springs, alimentation, etc., make the work very readable and useful.

Though Dr. Bartholow's prescriptions are often faulty, so far as their Latin is concerned, and several errors in composition are apparent, there is very little that can be adversely criticised and much to be praised; and in spite of the fact that he has several formidable competitors, we have no doubt the book will have a large sale.

**A COURSE OF PRACTICAL INSTRUCTION IN ELEMENTARY BIOLOGY.** By T. H. HUXLEY, LL.D., and H. N. MARTIN, B.A. 2d Edition, pp. 279. Macmillan & Co., London and New York. 1876.

THIS is intended as a laboratory guide to elementary biology, and comprises a good deal of information concerning the lower forms of plant and animal life, together with concise directions that will enable the reader to easily verify all statements which the authors make. Commencing with a description of the peculiarities of the *Torula* or yeast-plant, and its behavior in the presence of reagents, the authors proceed to consider the *Protococcus*, the amœba, colorless blood-corpuscles, and bacteria. After these they ascend to moulds, stone-worts, ferns, the bean-plant and the bell animalcule. From these again they advance in the life-scale to polypes, mussels, crayfish, and lobsters; and conclude with a very complete anatomical description of that favorite martyr to physiological science—the Frog.

The work is entirely practical, and should be one of the first books read by the student of natural history, and by the student of medicine who desires to rest his later physiological studies upon a sound elementary basis.

**ON THE TREATMENT OF ECZEMA.** By R. W. TAYLOR, M.D., Physician to Charity Hospital American Clinical Lectures, Vol. II., No. II. G. P. Putnam's Sons. New York. 1876.

THIS is a tract of twenty-eight pages upon an extremely important topic. Eczema, comprising as it does at least one-fourth of all the cases of cutaneous disease which come under the notice of the practitioner, is a subject upon which too much cannot be written, provided the writer is a man not only of experience, but one who profits by his experience. The monograph before us, a clinical lecture, chiefly considers the therapeutic aspects of infantile eczema, a subject which heretofore has not received from writers the attention it deserves. Very properly differing from the views of the German school, which considers eczema a purely local affection, and which usually treats the disease by external applications alone, the author pays a good deal of attention to the concomitant constitutional derangements, and recommends the internal use of mercurials, iron, cod-liver oil and arsenic, according to the indications presented by each individual case. He points out, however, the importance of judicious external treatment, but insists that this also must be governed by the stage, aspect, etc., of the eruption, and that a mere routine treatment will give the usual routine, that is, unsatisfactory results. For particulars we must refer the reader to the original, and in so doing recommend its perusal, not only by the student and the general practitioner, but also by the specialist.

## Reports of Societies.

### NEW YORK PATHOLOGICAL SOCIETY.

*Stated Meeting, November 22, 1876.*

DR. C. K. BRIDGON, PRESIDENT, IN THE CHAIR.

#### MORBUS COXARIUS.

DR. LEWIS A. SAYRE presented specimens of morbus coxarius, with the following histories:

Minnie King, *et. 11*, Washington, N. Y. Father died several years since; mother living; child always delicate. About eight years ago it was noticed that her knee began to pain her continually, especially when she awoke in the morning; could not touch the ground with the foot. The disease ran the usual course of morbus coxarius in six months. An abscess formed about six years ago over the joint. This was opened and has discharged ever since; several pieces of bone have been discharged, one as large as the top of the thumb. Since this time five other abscesses have formed and opened. On admission, is terribly anæmic; can walk with crutches; six sinuses discharging copiously; limb adducted, flexed, and fixed. Excised Oct. 18, 1876.

Miller, *et. 14*. In 1873, after riding on a horse rake, complained of pain in the knee, which was thought to be rheumatism. Was laid up for some time; recovered so as to walk without much pain.

One year after, again injured himself by sitting upon the damp ground when overheated from husking corn. Was then seen by Dr. Olmstead, who diagnosed morbus coxarius, and applied an extension by weight and pulley; the joint soon became acutely inflamed. Was treated with an extension apparatus, but the disease progressed steadily. In fall of 1875 a large abscess was opened about one inch below the trochanter major. The discharge has continued since that time, and as the probe touched dead bone, and the boy was losing ground, excision was performed Oct. 19, 1876.

The latter case was the sixty-sixth one of operation of excision performed by Dr. S.

#### BACKWARD DISLOCATION OF THE TIBIA—CHRONIC DISEASE OF THE KNEE-JOINT—AMPUTATION.

Dr. Sayre presented a third specimen, consisting of an amputated leg removed from a girl twelve years of age, who had her right knee injured when seven months old, by being twisted in the cradle. Since that time she had suffered from disease of the joint, eventuating in a complete backward dislocation of the tibia and a useless limb. There were several sinuses communicating with the joint. On account of the age of the patient and the retardation of growth which would be occasioned by excision, Dr. Sayre decided to amputate; Esmarch's bandage was used, and a very small quantity of blood was lost.

#### TYPHO-MALARIAL FEVER.

Dr. Loomis presented a specimen taken from a patient of Bellevue Hospital, who was admitted on Nov. 10th, with a very unsatisfactory history. He came on board a steamer at Norfolk with the statement that he had been taken sick three days before. During the passage here he suffered from occasional diarrhoea, with an average temperature of 102, and a few hours before his removal from the vessel he was slightly delirious. At the time of his admission to the hospital he had a mild muttering delirium, an anxious expres-

sion of countenance, pupils slightly dilated and insensible to light, rigidity of muscles of the arm, marked rigidity of those of the back of the neck and of the back. This latter condition was so marked that he could be raised from the bed without any bending of the neck. The pulse was 68, temperature 104½ F., tongue brown and dry, and abdomen markedly retracted. There was no diarrhoea after admission, and no tenderness of abdomen at any point. There was no vomiting during his stay in the hospital. The next day remained at the same standard, except a slight and temporary reduction as the result of cold applications to the surface. He never complained of any pain in his head. On the third day after admission his temperature at one time was reduced to 102° F. for a number of hours, and after a large dose of bromide of potassium.

The symptoms were such that no positive diagnosis could be made. The rigidity of the muscles, pulse, retraction of the abdomen, and absence of abnormal tenderness and of diarrhoea, favored the supposition that the case was one of cerebro-spinal meningitis. On the contrary, the character of the pulse and temperature were not such as were ordinarily met with in that disease.

From that time (the 14th) the rigidity of the muscles increased, the patient lapsed into a decided typhoid condition, and died on the 17th.

At the autopsy no inflammatory exudations were found, either in the brain or spinal cord—in fact, there were no evidences of cerebro-spinal meningitis; but on examining the intestines, there were found, in the neighborhood of the ileo-cæcal valve, ulcers resembling those of typhoid fever. These differed, however, from the ulcers of typhoid fever in two or three particulars. There was no abrupt rising of the edges of the ulcers, but rather an inversion of them—the apparent result of an undermining of the subjacent mucous membrane. Then again, at different points of the ulcers there was pigmentation, and the ulcers themselves were in different stages of development. In some cases the follicles were simply enlarged, in others there was an extensive removal of tissue, while in others cicatrization had commenced, and in a few this cicatrization was complete. In every respect these changes correspond to those described by Dr. Woodward, of Washington, as the distinctive lesions of typho-malarial fever.

The liver was enlarged, and presented the appearances which are ordinarily met with in malarial fevers. The spleen was enlarged, but not markedly softened. The heart was flabby and soft. The mesenteric glands were slightly enlarged.

In answer to a question from Dr. Heitzmann, Dr. Loomis stated that the disease received its compound name from the fact that it combined the symptoms and lesions of the two fevers.

DR. HEITZMANN, in the absence of the Microscopical Committee, volunteered a description of the microscopical character of the tumor of the breast presented at the last meeting by Dr. Sands. He expressed the opinion that it was a cysto-myxosarcoma.

#### CENTRAL OSTEO-SARCOMA OF FEMUR—LISTER'S ANTI-SEPTIC METHOD.

DR. L. A. STIMSON presented a tumor of the femur, which he removed by amputation through the middle third of the thigh, at the Presbyterian Hospital, Nov. 21st. The patient was a man thirty-seven years old, of healthy antecedents. He dates his trouble from a fall, received May, 1875, and followed by pain in the knee, lasting until Feb., 1876, when a swelling ap-

peared over the external condyle. This increased rapidly until the time of his admission to the hospital, Nov. 13th, when it was found to measure twenty and a half inches in circumference, and about nine inches in length, occupying mainly the anterior and exterior aspects of the lower half of the thigh. It was firm and resistant to the touch; no fluctuation; bony crepitus just below the surface in places; the skin was normal, but disproportionately warm, and traversed by large veins; no vascular souffle could be detected.

It was removed antiseptically (Lister's method), by the double flap operation.

It has now been divided longitudinally. The surface of section shows the skin, fascia, and muscles covering an encephaloid mass mottled with pink, yellow, and gray, resting on and united with the femur; it is friable, with numerous points of ossification; the inferior and deeper portion is occupied by a mass of spongy bone communicating with the interior of the condyles and the lower part of the shaft, the wall of which has been broken through. The tumor has also broken through the intercondyloid notch and sent a bony column half an inch in diameter, between the crucial ligaments, down to the anterior edge of the articular surface of the tibia. Otherwise, the articulation is unaffected, except at the upper cul-de-sac of the capsule, into which the neoplasm has penetrated from above, imbedding the patella and eroding its articular surface. One or two large isolated plaques of bone lie near the outer surface.

Microscopical examination shows the tumor to be composed of round and pusiform cells (many of them with double nuclei), and of large quantities of myeloplaxes, especially near the points of ossification. It is, therefore, to be classed as a *central osteo-sarcoma* originating in the condyles of the femur.

Dr. BEVERLEY ROBINSON exhibited mucous polyp of the nose, which he had removed by a wire snare.

#### COMPOUND FRACTURE OF FOREARM—SECONDARY HEMORRHAGIC EXTRAVASATION—AMPUTATION.

Dr. FINNELL presented the bones of the left forearm, taken from a young man aged sixteen years, who had sustained a severe compound fracture by a fall from a scaffold. Dr. Stephen J. Clark saw the patient immediately after the accident, and in company with Dr. Finnell dressed the limb in the usual manner, no untoward symptoms presenting themselves. On the second day after the injury an extravasation of blood occurred in the neighborhood of the elbow-joint, necessitating free incision for the relief of the tension. On the third day this extravasation increased to such an extent that amputation of the arm, just below the shoulder-joint, was necessitated. The patient, however, sank and died within a few hours afterwards. Both radial and ulnar arteries pulsated after the accident, and it was a matter of conjecture whence came the blood which so extensively infiltrated the tissues. The friends of the patient were much dissatisfied at the delay of the operation, maintaining that, had the amputation been performed sooner, life might have been saved. Dr. Finnell maintained that, under the circumstances of the case, the complication could not have been foreseen. Dr. Post concurred in the latter view, and at the same time suggested that the source of the hemorrhage might have been explained by an anomalous distribution of the arteries. In fact, not infrequently an independent artery accompanied the median nerve; such a vessel may have given rise to the extravasation. Dr. Briddon suggested that the only interference possible was the arrest of the hemorrhage.

Dr. Finnell maintained that the search was made,

with the result of finding a mere oozing inside of the lips of the wound.

#### POLYPUS OF RECTUM.

Dr. LEWIS SMITH presented a polypus of the rectum, which he had removed from a child aged four years, who had been treated by a number of physicians for prolapsus ani. On careful examination the diagnosis was made with perfect ease, and the operation by ligature relieved all the disagreeable symptoms at once.

#### HYSTERICAL VAGARIES.

Dr. AUSTIN FLINT presented some specimens, which were supposed to be entozoa discharged from the mouth of a female.

On motion, Dr. Dalton was invited to examine them and report the results at a future meeting.

#### SARCOMATOUS TUMOR OF TRAPEZIUS MUSCLE.

Dr. Post presented a tumor removed from the shoulder, and which had been developed in the midst of the fibres of the trapezius muscle. An examination by Dr. Stimson showed it to be a spindle-cell sarcoma.

Dr. Post presented a second specimen, which was a portion of a mammary tumor which he removed by operation from a woman four weeks before. At that time she presented a tumor with ulcerating surfaces and doubtful appearance. The axillary glands were unaffected. Dr. Satterthwaite examined a portion, and pronounced the growth that of adenoma. It was accordingly removed. Since that time Dr. S. examined the specimen more carefully, and found in different portions the commencement of epithelioma. It was quite evident that the tumor, from being at first benign, was becoming malignant.

Dr. Post exhibited a third specimen, consisting of a crushed foot removed by Quimby's amputation. Dr. Post remarked that the method differed from Symes and Pirogoff's method in the fact that it left the tibia and fibula intact. The operation had been performed twice by Dr. Quimby, once by Dr. Gouley, and once by Dr. Buck. The advantages of this operation are, that the end of the tibia is not interfered with, and that the growth of the bone is not arrested. Dr. Post then described the operation in detail.

#### EXTIRPATION OF RECTUM.

Dr. BRIDDON presented a specimen of extirpated rectum, with the following history, for which he was indebted to Dr. Wm. Kelley, House Physician to the Hospital Department of the Colored Home.

Eliza Walker, aged forty-five; mulatto; single; housekeeper. Admitted to hospital-service of Dr. Briddon. Mother died of consumption at age of thirty-five; is only child left of nine. Denies venereal. Has been a moderately temperate woman. With some slight exceptions, had been perfectly healthy up to three years ago. About that time commenced to have some pain in the small of her back; as she was not otherwise troubled, she thought nothing of it. Last September she noticed a small, very painful growth near the anus, which continued to grow until it attained the size of a half-dollar; complained also of a continual burning sensation in the rectum, pain in defecation, and frequent desire to urinate. Bowels at no time constipated, blood frequently discharged with stools; considerable tenesmus. About six weeks before admission the outside growth, nature of which is unknown, was removed.

On admission, August 11, 1876, patient's general health appears to be good. Thinks she has lost some

es during the last six months. No cough; appetite good; tongue clean; heart and lungs healthy. Uterus somewhat enlarged (sound passing to a depth of three inches) and freely movable. Through the posterior wall of the vagina a slightly indurated and irregular mass can be felt in the rectum. Upon rectal examination, a slightly prominent, somewhat nodular growth can be felt completely surrounding the gut and extending from a short distance above the external sphincter upwards about one and a half inches. The upper margin could be easily reached with the index finger and was quite abrupt in outline. The rectum was freely movable, showing that the surrounding connective tissue was uninvolved. The calibre of the rectum was reduced but little.

September 12th.—Patient re-examined. The mass above described is noticeably larger, and has extended in an upward direction to extent of nearly an inch, reaching above the internal sphincter about two and a half inches. Rectum still movable, and growth confined to walls of gut.

November 17th.—Examination to-day reveals, in addition to above-noted points, an enlarged lymphatic gland to patient's left, and just above the morbid mass.

Operation was performed November 20th. With the object of preserving the external sphincter, the anal perineum was split up by an incision, reaching from immediately behind the fourchette to the point of the coccyx; the anterior and posterior divisions of this incision were united by carrying the knife along the mucous membrane about one-quarter inch above anal aperture; loops were then passed through the skin-flaps on either side and through the end of the gut; the insertions of the levator were divided by the knife, which was then laid aside, and the deeper connections were severed by the fingers, aided by the handle of the scalpel and the blunt-pointed scissors. This separation was tedious and difficult; it was easy to separate the wall of the vagina from that of the rectum as high as the point where the peritoneum is reflected from one to the other; but the posterior connections high up in the concavity of the sacrum were unyielding, and it was only after considerable traction that the sound intestine at that point could be brought down level with the perineum; as soon as this was accomplished the gut was partially divided in front and attached by suture to the surrounding skin, the further division was made a little at a time, securing bleeding vessels and the gut to the adjacent skin, until the whole was fixed in position by nearly a dozen sutures.

The free surface of the growth was somewhat nodular, grayish pink in color, with points of ulceration, and slight hemorrhages here and there. Upon section the morbid process was found to involve chiefly the mucous membrane, which was much thickened and of purplish color. The muscular coat was considerably hypertrophied, particularly posteriorly; the connective tissue surrounding the rectum was perfectly normal in appearance. In it was found the enlarged lymphatic gland previously felt upon rectal examination. This gland was the size of a large pea and yellowish white in color, and upon section was found to be in a state of cheesy degeneration. A microscopic examination revealed a predominance of cylindrical epithelium, with a marked tendency to the formation of tubuli. The connective tissue was considerably infiltrated with small round cells. The lymphatic gland contained chiefly fatty detritus and tablet of cholesterine.

Diagnosis.—Cylindrical epithelial cancer.

DR. SATTERTHWAITTE, as a member of the Microscopical Committee, made a few remarks upon the dis-

eased breast presented to the Society at its last meeting, by Dr. Sands. The following is the full report:

The diseased material that occupied the position of the normal gland structure was extremely soft—almost diffident, of a yellow and red color, and looked like the interior of a gland that had undergone degeneration. This softened mass was separated from the surrounding tissues by a distinct capsule. At a few points no softening had taken place, and at two of them small nodules were found lying loosely attached in capsules. One of these nodules was lobulated, some of these lobules being covered with smaller growths. The other was exceedingly vascular, and of a pale pinkish color. Microscopically the last-named mass was found to be composed of a network of large vessels with delicate walls, and between them was an abundance of extravasated blood, with dense collections of lymphoid corpuscles in the immediate proximity of the vessels. The vessels themselves were densely packed, either with blood corpuscles or granular matter. In another portion of the diseased growth the vessels were not very numerous, and the tissue was composed almost wholly of bodies like the lymphoid elements, separated from one another by a definite amount of intercellular substance. These qualities are such as would justify its being classed under the sarcomata: the two nodules were probably growths which had taken place inwards from the walls of cysts that had existed in an early period in the history of the disease. The fluid was gradually displaced by the growths. Such formations are not uncommon in sarcomata and adenomata, and probably the nature of their origin in each instance is about the same. It seems to be doubtful if we are prepared to distinguish, in a clinical point of view, these sarcomata from adenomata, even when they have a comparatively pure histological character. It is not impossible that the theory of Dr. Hodgkins holds as well with reference to the great mass of the tumor as with reference to the smaller, lightly attached nodules. It may in this light have also originated from a cyst-wall, and, growing outwards, displacing the fluid, have united itself to the cyst-wall. The normal tissue of the gland may then have become compressed and obliterated. The prognosis is usually regarded as good.

#### EPITHELIOMA OF THE LARYNX.

DR. SATTERTHWAITTE also reported that the scrapings from the laryngeal growths, presented by Dr. Beverley Robinson at the last meeting of the Society, gave evidences of epithelioma, as the surface was densely coated with epithelium, and there were the collections of epithelial bodies in nets, which are regarded as typical of epithelioma.

LOUISVILLE MEDICAL COLLEGE.—A student of the Louisville Medical College has sued that institution for the amount of the fees paid for that part of the session which he has not attended. The substance of the complaint is that the Louisville Medical College is not a first-class institution, that its curriculum of studies does not embrace the requisite number of branches, that the instruction is insufficient, that the college is not legally organized, and that he was induced to enter the school under fraudulent representations and promises. It will be recollected that this is one of the institutions by means of which the short-term system obtained such an unenviable notoriety. The affairs of the school have given rise to a good deal of censure, and now that they are the subject of legal inquiry, the truth or falsity of the various statements will doubtless be fully set forth.

## Correspondence.

LISTER'S ANTISEPTIC METHOD IN  
OVIARTOTOMY.

THE following letter, addressed to Dr. J. Marion Sims, will sufficiently explain itself:

St. JOSEPH, MO., Dec 19, 1876.

DR. J. MARION SIMS.—*Dear Sir:*—On the 7th October last I performed my second ovariectomy. Being favorably impressed with "Lister's antiseptic method," I determined to use it, as far as practicable, with the rude appliances at hand, using an ordinary Richardson spray-producer. The atmosphere of the room was thoroughly carbolicized, and the same plan carried out in operating as you describe in your case.

The patient was forty-two years old. The tumor multilocular; left ovary without adhesions; small pedicle; and weighed twenty-four pounds. My patient recovered rapidly, and returned home well the fifth week after operation.

Until I saw your article in the RECORD of the 9th December, I supposed that others had already adopted the antiseptic method, not regarding myself as a pioneer.

Believe me, dear Dr. Sims, most truly yours,  
J. M. RICHMOND, M.D.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—In a previous issue of the RECORD, Dr. Sims, in an article on *Lister's Method in Ovariectomy*, says he has "often wondered why it had not been used in ovariectomy," and from his remarks would seem to claim priority in the use of Lister's method in that operation.

I would state that three years ago, in an ovariectomy, I began the use of Mr. Lister's spray-producer—one constructed by Gardner, of Edinburgh, containing a two per cent. solution of carbolic acid, but from a stopping of the instrument could not continue the spray until the completion of the operation; but the after-care of the wound was in conformity with Lister's ideas. The patient made a good recovery, and at no time showed any marked febrile excitement; pulse never above one hundred.

Eleven weeks after the operation, after taking a long ride from the country, where she had been for a visit, she was suddenly attacked with acute diarrhoea and died two days following.

Nearly a year ago, in performing an ovariectomy, I made use of Lister's method, using great care to observe the minutest details in every way.

This case proved fatal the fifth day, but there was no symptom of abdominal disturbance or tenderness; patient died from continuous vomiting.

In 1867 I witnessed some of Mr. Lister's first experiments in antiseptic surgery at the Glasgow Infirmary; later I have seen the more perfect working of his great discovery at the Royal Infirmary in Edinburgh. From the first I could but think favorably of the method, and practised it to the best of my knowledge in the extensive surgical practice that came to my hand while physician to the Eastern Turkey Mission.

Later, as I became more fully acquainted with the mode and materials used, learned the necessity of the greatest care in following every detail and seeing the admirable results, the freedom of wounds from pus,

the little constitutional disturbance, the absence of inflammation in surrounding parts—even the very border of a wound, perhaps the flap of an amputation not tinted half an inch from the edge, I could but have faith in it, and consider it suitable and necessary in every surgical operation where an opening was made in the tissues. As I found that wounds penetrating the joints—though an escape of synovial fluid continued for some time—kindly healed, that in fact a joint could be opened with perfect impunity, and no danger of pus need be apprehended or of an anchylosis following, I became enamored with it, and for the last four years have practised it with the greatest satisfaction in nearly every surgical case that has fallen to my hand, fully believing that Joseph Lister has made the great advance of the century in surgery, and that if we are to see immediately great improvements in this science, it will be in the means employed and the manner we care for our surgical wounds.

JAMES ANDREW MILNE.

OSWEGO, 16th Dec., 1876.

## FRACTURE DRESSING.

TO THE EDITOR OF THE MEDICAL RECORD.

I DESIRE to call the attention of the medical profession to a fracture dressing which, as I conceive, fulfils all the indications sought in treating broken bones, being a perfect retainer.

The dressing consists of plaster-of-Paris splints, retained by adhesive plasters and a roller bandage.

To illustrate, we take a simple fracture of both bones of the leg (tibia and fibula) near the middle third, cut two strips of good adhesive plaster, in width one-third of the limb's circumference, and twelve to fifteen inches long, warm and adjust each to the lateral sides of the limb from the fractured point down smoothly over the malleoli, retaining them in place by a roller bandage. The fracture being properly adjusted, can be so retained by weight and pulley, the compound pulley or any other force attached to the distal ends of the adhesive straps, the body being fixed.

The whole leg is now put up snugly in a roller bandage from the foot to the knee, the plaster-of-Paris splints are next adjusted to each lateral side, and over all a second roller-bandage is carried, securing snugly and smoothly to the limb the now plastic splints.

The splints are made of strips of cotton flannel, in width one-third the limb's circumference, and in length from the foot to the knee. Each strip is rolled in dry plaster-of-Paris, and when properly rolled and wet is ready for adjustment, as above stated. I use from three to eight of these strips on each lateral side, according to the development of the limb and the character of the fracture.

The plaster soon sets, or becomes hard, and a perfect moulded splint is obtained. In readjusting the splint or splints, bare the limb of all dressing except the adhesive strips used as an attachment for the extending force. Cut two more strips of adhesive plaster, two to three inches wide, and twice the length of the splints, fold each lengthwise upon itself, having the adhesive side out; when folded each strip of plaster is one to one and a half inches wide. These folded strips are warmed and fitted to the inside of each lateral splint lengthwise, and the splints returned to their places as when moulded on the limb. That part of the folded adhesive plaster which extend beyond the ends of the readjusted splints is turned back on the outside of the

plints and the whole secured by a roller bandage, cut off the extending straps close to the foot, and the dressing is completed.

I use the above dressing in fractures of all the long ones, not excepting the clavicle, and think it an improvement on Dr. L. Sayre's adhesive-plaster dressing in fractures of the clavicle. Yet I am indebted to Dr. Sayre for the above idea, although I am not aware if any one else has used the two plasters, plaster-Paris and adhesive plaster, in conjunction, as I have stated above, in cases of fractures, prior to myself.

CHAS. E. BEARDSLEY, M.D.

OTTAWA, Ohio.

CINCHO-QUININE.

TO THE EDITOR OF THE MEDICAL RECORD.

MY DEAR SIR:—Dr. FOI'ST's interesting letter in the RECORD of to-day induces me to again direct attention to the merits of a new preparation of Peruvian bark, which, although it has been before the profession some seven years, may not have received from the fraternity that recognition to which, in virtue of its many good qualities, it is unquestionably entitled. I refer to cincho-quinine.

Careful analysis proves it a quadruple compound, containing *quina*, *quinidia*, *cinchonina*, and *cincho-ida*, so that nothing is needed, save clinical evidence, to prove that it possesses in large degree the valuable properties of the universally used cinchona.

The tenor of Dr. F.'s communication is mainly the absence of usual cinchonol manifestations as a result of combining the time-honored sulphate with hydrobromic acid—an excellent want, undoubtedly—and it is *this very virtue* which is so strikingly prominent in cincho-quinine. It does not produce *cinchonism* in the ordinary acceptance of that term, innitus aurium, vertigo, etc., but its specific effects are manifested in a peculiar *visual* derangement, varying from slight blurring to complete diplopia. In some sensitive patients fifteen or twenty grains will suffice to produce the latter symptom, while one-fourth that quantity will occasionally give rise to decided cloudiness of vision. Whether these results—which are transient and may be regarded as conclusive evidence of its constitutional action, and when fully pronounced, just as effective, therapeutically as a genuine quininism—are due to any change in the nervous or vascular condition of the retina, to a direct action on the origin of the optic nerve, or to a general effect on the cerebrum, is for some competent physiologist or ophthalmologist to determine.

It has, too, other advantages. It is much more unlikely to get up gastric disturbance; the constitutional effects are less objectionable; it is comparatively tasteless; and lastly, but far from least, the tenor of *cost* alone is a strongly marked point in its favor, the present price of the sulphate being three dollars and ten cents per ounce at wholesale, while that of cincho-quinine is only one dollar and seventy-five cents. The dose is the same.

As an antiperiodic I have employed it almost exclusively for years, and with the greatest satisfaction, having met but a single instance of intermittent disorder which it failed to control. That exception was the most obstinate case of periodical fever I ever encountered; contracted in New Mexico, of four years' duration, rebellious to quinine to the extent of deafness, blindness, and convulsions—not given by myself, however—and which, under the influence of full doses of Fowler's solution, was so held in abeyance that I began to indulge in felicitations regarding a

cure, when, on the *fortieth* day, the chill reappeared and patient passed from under my observation. Whether the poor fellow afterwards resorted to that heroic specific—a bullet through the brain—I have not to say. As a *tonic* my experience has not been sufficient to warrant me in advancing a positive opinion, though testimony is not wanting, from other sources, to show that it suffers nothing by comparison with the sulphate in this regard. But as an antiperiodic I speak whereof I know.

Yours very cordially,

J. B. MATTISON.

THE LATE DR. GEO. WILKES.—At a stated meeting of the New York Academy of Medicine, held on Thursday evening, Dec. 21, 1876, a committee, consisting of Drs. Austin Flint, C. R. Bogert, and F. A. Burrall, presented the following resolutions, which were unanimously adopted:

*Resolved*, That the departure from this life of the late George Wilkes, M.D., is a loss to the Academy of a valued Fellow; to the medical profession, of a member distinguished for his attainments, his urbanity, and strict sense of honor in all his professional relations; to his patients, of an able, faithful, and sympathizing physician; and to society, of one who exemplified the characteristics of the true gentleman.

*Resolved*, That the Secretary of the Academy be instructed to convey to the family of the deceased an expression of profound sympathy for the great calamity which they have sustained in the loss of an honored and devoted father and brother.

S. S. PURPLE, M.D., President.

W. T. WURTE, M.D., Secretary.

THE LATE DR. J. S. THEBAUD.—At a stated meeting of the New York Academy of Medicine, held on Thursday evening, Dec. 21, 1876, a committee, consisting of Drs. J. B. Reynolds and T. C. Fennell, presented the following resolutions, which were unanimously adopted:

*Whereas*, It has pleased an all-wise Providence to remove from his sphere of usefulness, and in the prime of his manhood, our late associate member, Dr. Julius S. Thebaud.

*Resolved*, That the members of the New York Academy of Medicine deeply mourn his premature and very sad death.

*Resolved*, That the Academy deplore the loss of a highly esteemed member, a distinguished surgeon, and a man whose generous qualities endeared him not only to his professional brethren, but especially to patients and friends.

*Resolved.* That we tender our deepest sympathies to his bereaved family in their great affliction.

*Resolved.* That these resolutions be published in the medical journals of this city, and that a copy of them be transmitted to the family of the deceased.

S. S. PURPLE, M.D., President.

W. T. WHITE, M.D., Secretary.

**EYE INFIRMARY IN JAPAN.**—On the 20th of November the Tokio Eye Infirmary was opened by Dr. D. B. Simmons. It is a two-storied brick building, and contains a dispensary and consulting-room, besides permanent accommodations for twelve patients. This is the first and only institution of the kind in Japan. In the evening a dinner was given in honor of the occasion. About forty persons were present at the dedication, and addresses were made by Dr. Simmons and Mr. Kuki, vice-minister of Education.

**HYDROPHOBIA IN THE HORSE.**—A horse recently died of hydrophobia in this city.

DR. L. R. LONGWORTH retires from the editorship of the Cincinnati *Clinic*. During his connection with that journal he has made it one of the sprightliest of its kind in the country, and now that he feels his work is done, we congratulate him upon the assumption of more congenial labors.

THE *Quarterly Journal of Inebriety* issued its first number December 1, 1876. It is published under the auspices of the American Association for the Cure of Inebriates, and is edited by Dr. T. D. Crothers, of Binghamton, N. Y. The present number contains the anniversary address; an article on the increase of inebriety, by Dr. Beard; an analysis of one hundred cases of inebriety; and miscellaneous articles. It is well printed and presents a creditable appearance.

**COFFEE TAVERNS IN LONDON.**—The establishment of coffee taverns in London is the latest phase of the temperance movement in that city.

DR. WILLIAM REGNAULT, of Paris, died November 25th, as the result of diphtheria, with the poison of which he was inoculated during the performance of tracheotomy. He was forty years of age.

**THE LAW OF LABEL.**—The *Cork Constitution*, in commenting upon the recent libel suit against the *Medical Press and Circular*, says: "We can conceive nothing more disastrous to the interests of society than that the force of public opinion, expressed through the press, should be suppressed through fear of legal consequences, annoyance, and expense."

**TYPHOID FEVER IN PARIS.**—The mortality from typhoid fever is still alarmingly great, being 104 last week.

**SMALL-POX.**—There is a serious epidemic of small-pox in Liverpool.

**SHORTER HOURS FOR DRUGGISTS.**—The druggists of Great Britain are perfecting a plan for closing their shops at an earlier hour in the evening.

"PILL ROW."—Thirty-fourth street is, to-day, in the number of physicians it contains, what East Broadway was in olden times. From this circumstance it is facetiously known as "Pill Row."

**BODIES BURIED BY THE CITY.**—The average number of bodies of infants received at the Morgue and buried by the city, per day, is about twelve, mostly from tenement-houses. The number of bodies of adults is very much smaller than for many years.

**NEW JOURNALS.**—The Louisville *Medical News* says: "Evidences of new medical journals for 1877 are rife. It will soon be in order for the Boston *Medical Journal* and the New York *MEDICAL RECORD* to read the riot act."

As far as we are concerned we give the editor of the *News* due credit for his foresight, for the following was in type when we read the above:

"Several new medical journals are announced for the coming year. The reasons given are, 'in consequence of a want long felt by the profession,' etc. The shoe is so apt to be on the other foot, that at the end of a year or two the wants of the journal are much in excess of those of the profession. The latter may be considered, for the sake of the argument, an unappreciative set in any event, but that is no reason why we should not hope for the best."

**HOSPITAL PATIENTS.**—There is a great want of good clinical material in the hospitals of this city, but judging from the attempts made to obtain it, we have no doubt that medical charity will prevail.

**HEALTH OF PHILADELPHIA.**—The Report of the Board of Health of Philadelphia for the year 1875 has just been published.

**MODES OF ADMINISTERING IODINE.**—Dr. E. Seguin writes: "The danger of administering pure iodine in the therapeutics of children, and of persons evidencing scrofulous and tubercular diathesis, was pointed out with great force by Jules Simon in one of his clinical lectures at the Hospital for Children in Paris. His prominent points were:

"Tincture of iodine must not be employed pure to tuberculous children. It should be diluted either with glycerine or with some unguent. Neither iodide of potassium nor iodide of iron should be given to children under two years of age, except perhaps in case of acute hereditary syphilis. It may be given to the nurse. Elder children bear the drug well. Iodoform is of great service in case of ozæna, etc."—*The Moniteur Thérapeutique*, Aug. 7, 1876.

"Nothing is said of iodine used in its natural form of *evaporation*, both inwardly and externally. The practice of a great surgeon (Lister) has called the attention to iodized cotton as an antiseptic dressing. In my experience, this medicated cotton, or the carbol iodized cotton, controls better than any other previously known local remedy the enlargement of the submaxillary glands which accompanies the second stage of diphtheria.

"I beg leave to say, also, that for more than fifteen years, I usually prescribe the inhalation of iodine in forms whose formulary may be found in many drug stores of this city. The most usual of these forms being that of a pillow containing aromatic plants, say sea-weeds, black walnut or fern leaves, etc., according to secondary indications. In this pillow is introduced a little bag or satchel containing a drachm or so of iodine, in as much of bran as will prevent the too rapid evaporation of the drug. When the satchel does no more smell of iodine, it is refilled, and when the pillow begins to smell the pus-like odor peculiar to those cases, the herbs are also renewed. Let us remark *en passant* that the alteration of both is in proportion to the gravity of the affection. The pillow must be soft, and broad enough for the head and chest to remain upon it during the night tossings. The urine has to be tested for albumen during this treatment."

**A HINT FOR POLYPHARMACISTS.**—An Irishman complained to his physician that he stuffed him so much with drugs that he was sick a long time after he got well.

## Original Communications.

## EAR-ACHE,

OR CATARRHAL INFLAMMATION OF THE MIDDLE EAR.  
A NEW METHOD OF TREATMENT.

By SAMUEL SEXTON, M.D.,

NEW YORK.

SURGEON IN CHARGE OF THE N. Y. EAR DISPENSARY; MEMBER INTERNATIONAL OTOLOGICAL CONGRESS; AMERICAN OTOLOGICAL SOCIETY, ETC., ETC.

For the purposes of this article, catarrhal affections of the middle ear will be divided into two classes, namely: acute and chronic. I shall here confine myself to the former, reserving for a future occasion the treatment of the chronic variety. It is in the acute form of the disease that the inflammation is mostly attended by that symptom by which the affection is generally known as ear-ache.

## ACUTE CATARRH OF THE MIDDLE EAR.

The causes, symptoms, etc., of this disease are so well set forth in the treatises on otology, which are accessible to all, that I shall in this article only refer to them incidentally, my object being to introduce a method of treatment which has been attended with favorable results, although it has been but a short time—four months—the subject of my attention. I venture, however, to offer my observations to the profession, crude as they are, in order that others may determine their value by independent experiment.

The frequency of ear-aches among that large class of sufferers, young children, certainly appeals very strongly to all of us to hasten to make known any means which shall benefit them. The case which first led to these remarks was as follows:

CASE I.—Philip H., aged eighteen, a stout healthy lad, whose occupation was that of office-boy, came to the New York Ear Dispensary for treatment September 13th, 1876, with catarrhal inflammation of the middle ear, both sides affected. Three weeks before, he "caught cold," and suddenly became deaf; his ears felt "stuffed." Pain or noises were not a marked symptom. This deafness continued for a week, when, diving in the water while bathing, he felt a sharp crack; immediately he could hear quite well; but after the lapse of two days the deafness gradually returned.

*Examination.*—Meati very large; the memb. tym. were both inflamed and slightly bulging; short processes prominent. The inner extremity of the meatus externus on both sides was involved in the inflammatory process. The height of the disease had been reached, if not passed.

The mucous membrane of the throat was much congested; uvula elongated and enlarged. Hearing distance, as measured by a watch which can be heard by the normal ear eighty-four centimetres, R.  $\frac{9}{34}$ , L.  $\frac{9}{34}$ . The Eustachian tubes were not permeable by the Valsalvian experiment, but were made so by means of a catheter. Medicine was ordered for the general symptoms, and syringing with warmed water was used at each visit.

Sept. 14.—Hearing, R.  $\frac{3}{34}$ , L.  $\frac{6}{34}$ . Catheterized both e. t. Condition of both ears about the same.

Sept. 16.—Hearing, R.  $\frac{1}{34}$ , L.  $\frac{7}{34}$ . Catheterized.

Sept. 19.—Hearing, R.  $\frac{6}{34}$ , L.  $\frac{3}{34}$ . By this time, hav-

ing thought much over the statement made by the patient at his first visit, namely, that after the immersion of his head under water he heard well for a few days, I concluded that the improvement in hearing was caused by the pressure upon the m. t. I therefore decided to make gentle pressure upon the m. t. by means of condensed air. The result was hearing, R.  $\frac{2}{34}$ , L.  $\frac{1}{34}$ .

Sept. 20.—Syringing brought away from both ears some exfoliated epidermis and cerumen, after which hearing was R.  $\frac{2}{34}$ , L.  $\frac{2}{34}$ . Condensation of air was then made as before, and the hearing found to be R.  $\frac{2}{34}$ , L.  $\frac{2}{34}$ .

Sept. 21.—Patient improving. Hearing, R.  $\frac{2}{34}$ , L.  $\frac{2}{34}$ . After condensation or pressure, R.  $\frac{2}{34}$ , L.  $\frac{2}{34}$ .

Sept. 25.—Improving. Hearing, R.  $\frac{5}{34}$ , L.  $\frac{2}{34}$ ; after pressure, R.  $\frac{2}{34}$ , L.  $\frac{1}{34}$ . The case continued under treatment until October 7th, syringing being required every few days until the old skin had completely exfoliated from the m. t. and neighboring parts of the m. externus. The pressure was made at each visit, and was never attended with any pain. Towards the last, rarefaction of the air in the m. externus was also resorted to, in order to prevent adhesions. I resolved in future to begin this earlier. I omit many details of the ordinary treatment in this case, in order to not occupy too much space—my object being to show the results of condensation and rarefaction of air in the m. e.

A cut is here introduced, showing the instrument I have devised for the treatment of aural cases by this method.

It consists of a soft rubber bulb, C, connected by a flexible tube, B, to a hard rubber nozzle, A, which is somewhat olive-shaped and adapted to fit into the entrance of the external auditory meatus. When used, the nozzle is held to the ear by the left hand, and pressed against the opening with sufficient force to make the fitting as nearly air-tight as possible; while the bulb is held in the right hand, to be manipulated as desired. When using the instrument, it is of course never to be forgotten that the membrana tympani is ordinarily never stimulated to action by a greater force than the wave pulses of the air, and that the organ of hearing may be injured by too great force. When thus carefully used, the danger of injury is not so great as by Politzer's inflation, especially in cases where the E. tubes are freely open. When the instrument is to be used for suction—rarefaction—for instance, to draw out a membrane much depressed, the bulb is simply collapsed by pressure of the right hand before the nozzle is applied to the ear. Upon removing the pressure of the hand, the bulb, by its own elasticity, gradually resumes its expanded condition—thus rarefying the air in the m. externus. If it is desired to give the m. t. and ossicula motion, the bulb is alternately compressed and expanded while the nozzle is in contact with the ear.

The remark is here suggested that if the object of forcing air into the cavity of the tympanum, by means of the catheter or Politzer's experiment, is to remove

secretions from that cavity, the result may be frequently of quite an opposite character, *i. e.*, the mucus of the Eustachian tubes may be driven into the tympanic cavity.

If the contents of the tympanum be of such consistence as to be readily driven out at all, it may in many instances be accomplished, to some extent, by pressure upon the m. t. from without. I am satisfied that in many cases paracentesis has been avoided by this means, as I do not find this operation advisable in so many cases as formerly, and I am of the opinion that in the greater number of cases of acute catarrh of the middle ear the operation should be avoided unless rupture of the m. t. is imminent from pressure behind the drum-head. Where the inflammation is high, of course, leeching is not to be omitted; and the instillation of water, warm as it can be borne by the patient, is applicable to nearly all cases. I find among the poor, where this affection is very prevalent, that quinia, iron, etc., are more frequently indicated than local depletion, especially as many cases are not seen until the most active stage is passed.

The subacute form of catarrh may often go on to perforation of the m. t., before the patient is aware that any serious result of a cold is likely to ensue. The following case further illustrates the subject:

**CASE II.**—H. F., aged sixteen, consulted me on October 26, 1876, for ear-ache. She is a bright girl—brunette. Mother died of consumption at age of thirty-five, also some of her mother's sisters. She has menorrhagia, and some symptoms of pulmonary disease. She is subject to frequent attacks of catarrh, and has suffered from ear-aches since six years of age. She frequently has sore throat.

For the past week she has had severe pain in the left ear, with singing noises.

**Examination.**—Both m. t. dull; mucous layer injected; left m. externus at inner extremity quite red and tender, with the skin exfoliating. Tonsils engorged, and the mucous membrane about the pharynx thickened and deeply injected. Both Eustachian tubes open. Hearing, R.  $\frac{24}{16}$ , L.  $\frac{24}{16}$ . After syringing both ears, pressure was made, after which hearing was R.  $\frac{24}{16}$ , L.  $\frac{24}{16}$ .

October 28.—Treatment continued; no pain.

November 11.—The same treatment has been continued daily, during which time she has had no pain, but noises in varying degree. The hearing at this date is recorded, R.  $\frac{24}{16}$ , L.  $\frac{24}{16}$ , being normal for the watch, and she can hear whispered words fourteen feet—the length of the room. Once, on the 29th of October, she felt a little dizzy after the operation, but no more than often occurs from syringing. During this time she had frequent exacerbations of the catarrhal difficulty, which were met by five-grain doses of quinine twice daily. Upon inspecting the left ear, there was seen, situated on the m. t., anterior to the handle of the malleus, a small, fatty-like substance, about the size of a grain of wheat in circumference; it appeared to occupy a space between the middle and external coats. The m. t. was quite dull, but otherwise looked well. The right ear was improving rapidly.

November 13.—She has taken fresh cold, and the right ear has been very painful all night; she could not sleep. Examination shows the posterior half of the m. t. to be bulged out, the anterior portion much inflamed with injected blood-vessels; the meatus at inner extremity denuded by exfoliation of the epidermis. After syringing, the whole membrane is red in color. Hearing, R.  $\frac{12}{16}$ , after pressure  $\frac{24}{16}$ .

November 14.—The myringitis well-marked, with light, stringy mucous discharge, indicating perfora-

tion. Noises very great. Pressure, which was not attended with pain.

November 17.—The treatment has been continued with such additions as the condition of the patient seemed to require for sore throat, etc. The perforation is well defined; the membrana tympani is clearing up; no discharge, but much singing noise. Hearing, R.  $\frac{12}{16}$ , which pressure increases to R.  $\frac{24}{16}$ .

November 20.—Condition much the same, but hearing improving, being, after pressure,  $\frac{44}{16}$ .

November 23.—Improving; no noises, no discharge; perforation smaller. Hearing, after pressure, R.  $\frac{24}{16}$ . Suction, as well as pressure, has been used for some days, and the membrane is nowhere adherent.

November 26.—Slight singing noise again.

November 28.—Noises ceased; perforation smaller; cone of light normal; hearing same.

December 4.—No noises or pain. Hears voice well. The perforation is very small. Hearing per watch,  $\frac{24}{16}$ . Treatment continued.

December 10.—Discharged well. The perforation is closed. Hearing about normal.

During the progress of the above case, the general condition required constant attention—in a word, she was a most favorable subject for catarrhal inflammations.

Space will only permit me to introduce here one more case bearing upon the subject.

**CASE III.**—Thos. C., aged fourteen. Came to me November 27, 1876. For one month has had ear-ache occasionally (left ear). Has increased of late and keeps him awake at night. The noises distress him very much, and interfere with his studies at school.

**Examination.**—The boy is in good health, otherwise than the catarrh of the middle ear. Throat but little affected.

Meati very large. Both m. t. dull; processes of malleus quite prominent; cone of light seen. Removed by syringing some dry and exfoliated epidermis from both ears. Hearing: R.  $\frac{24}{16}$ , L.  $\frac{24}{16}$ . Pressure and suction to both ears, after which hearing, R.  $\frac{44}{16}$ , L.  $\frac{44}{16}$ .

November 28.—Pressure and suction to both ears. Very little pain since last visit.

December 1.—The same treatment has been continued daily since last visit, during which time he has had no pain. After the operation, there is slight injection of the blood-vessels running along the handle of the malleus. Hearing, R.  $\frac{24}{16}$ , L.  $\frac{24}{16}$ .

December 2.—Noises have ceased; he hears voice better; no ear-ache.

December 4.—No ear-ache; hearing improving; the short processes on both sides still quite prominent. The Politzer experiment shows both e. t. to be open. The patient was to report again if pain or noises returned. As he has not done so, I infer that the benefit has been lasting.

In infancy and childhood, the difficulties in the way of using the catheter, or Politzer's experiment, are only too well known. But the cavity of the t. may be freed in some measure by pressure from without. My experience is that it always relieves the pain which results from inflammation and the accumulation of serum in the t., where the most free nervous distribution is to be found.

Adhesions can in no other way be so well prevented, or broken up when formed; for the movement of the m. t. may be kept up when other means cannot be resorted to. The extent to which this movement can be carried with benefit is considerable; and when we observe a membrana tympani so concave that it touches the promontory of the t. in one case, or is bulged out by secretions in another, we can judge somewhat of

the capacity of these parts for tension without injury. Sometimes the ear is too painful or tender to permit the application of the instrument; its use then is not to be thought of; but the inflamed membrana can be acted upon in most cases without pain or injury.

That perforation may occur when not expected by the appearance of the parts, and unattended by pain, is well known. Recently I examined the ear of a physician, and, to his surprise, informed him that the slight catarrhal stuffiness, which had scarcely attracted his notice, had resulted in a perforation.

In Case II. of this article, it will be observed that perforation had occurred in the right ear almost as soon as attention was again particularly drawn to the affected part.

It is not unlikely that the frequent (daily) pressure upon the m. t. in many cases may excite the movement of serum along the e. t. towards the pharynx, and thus keep the t. free of hurtful collections. That this is the natural outlet for the secretions of the t. cavity there can be no doubt. When tinnitus aurium depends upon the adhesions between the malleus and m. t., and between the ossicula and the stapes and fenestra ovalis, may not much benefit arise from exercising, as it were, this mechanism?

The air forced into the t. cavity through the Eustachian tubes does not perform this so well, and cannot be done with the same ease and gentleness.

The frequency of the applications must be determined by the results as derived from experience.

The congestion of the m. t. is not as marked after this operation as is sometimes the case after syringing—usually, there is none. The hearing power in nearly all cases of deafness will be increased in as great a degree as by any other means we are acquainted with, and in many instances benefit is found where other means do not avail. I am aware that many otologists have made valuable suggestions as to the use of condensed and rarefied air, but I believe none have recommended its use, in acute aural catarrh, in the manner here indicated.

If I have made mention of its use in cases where it has been used before, it is only to add my observations to those of others. Nor is it intended to be implied that a judicious use of any means of inflating the middle ear shall be used any the less in treatment.

In regard to chronic aural catarrh and its frequent attendant, tinnitus aurium, I shall give the results of my experience on a subsequent occasion.

## NINE INCHES OF BROOM-STRAW, WITH CALCULOUS CONCRETIONS, REMOVED FROM THE BLADDER BY LITHOTOMY.

By J. E. O'BRIEN, M.D.,

SCRANTON, PA.

This patient, a Frenchman, aged about forty, and married, was present at an operation of lithotomy which I made at his house one year ago for a young man aged twenty-three, from whose bladder I removed two stones of the size, respectively, of an almond and an almond kernel.

In the present case the patient tells his story as follows: One month ago, while working in the woods, he fell astride of a thorn, which entered his flesh in front of the fundament, and had since prevented his urinating freely. A medical gentleman had attended to him, passing the catheter, and sounding him frequently, but assuring him that there was "nothing

there;" meantime he was passing blood and pus per urethram.

On passing the sound I detected a foreign substance in the prostatic part of the urethra; it had not the resiliency of a thorn, but might, on a careless examination, have been mistaken for a band of cicatricial tissue or the mouth of a false passage formed by awkward attempts at catheterism. There was no scar on the perineum, nor could any thorn be felt per rectum. On the following day, November 14th, I cut down upon a grooved staff, held by my friend Dr. Fisher, as if for lithotomy; on arriving at the prostatic urethra I detected the end of a broom-straw, which I withdrew from the bladder, and found to be three inches long, with the distal end clean cut, and the other frayed and encrusted with concretions, showing that I had not broken it. On cutting into the bladder I discovered and removed a second piece four inches long, and a third piece two inches long, encrusted with concretions to the size of a No. 15 sound. This latter portion was the branching top of the broom-straw; it had lain in the bas-fond of the bladder in the most favorable situation for the deposit of concretions, while, of the other two pieces, one was held by the neck of the bladder, and the other stood obliquely within it. The operation was completed by the removal of a quantity of loose gravel from the bladder. The patient made a prompt recovery. He has volunteered no further information as to the entrance of the "thorn," and I deem it quite unnecessary to insist on any, or to hint to the readers of the *MEDICAL RECORD* the real route and mode which conveyed the foreign substance to its awkward situation.

## Reports of Hospitals.

### BELLEVUE HOSPITAL.

#### NOTES OF PRACTICE AND PECULIARITIES OF TREATMENT.

(CLINIC OF FRANK H. HAMILTON, M.D.)

#### REFRACTURING THE THIGH BONE—WHEN TO RESORT TO THE OPERATION.

The case before us was a child who had sustained a fracture of the femur near its middle portion. It had been treated by the use of short splints, and when first seen by the visiting surgeon, at the end of two weeks, union had taken place, but the fragments had united in such manner as to leave a marked deformity. Union in so short a time was believed not to be uncommon in a young subject. It was proposed to refracture the bone, and then dress it with a splint extending the whole length of the limb and reaching up on the body. The view was advanced that in cases of recent fracture the bone could be refractured with safety, for union would almost invariably take place; but in cases of old fracture, there was great risk of non-union if the bones were refractured.

#### FRACTURE OF THE BODIES OF THE VERTEBRÆ—GREAT DEFORMITY—RECOVERY.

A middle-aged man was presented who had sustained a fracture of the bodies of several of the dorsal vertebrae. The case was interesting in the following particulars: There had been no caries, no abscess, and recovery had occurred with only a slight paralysis of the right leg remaining. It was said that only a few

cases of broken back recovered, and that recovery was almost always accompanied by paralysis of the extremities below the seat of the fracture.

**FRACTURE OF THE CLAVICLE—DIFFERENT METHODS OF TREATMENT—AN INEVITABLE RESULT.**

There were four cases of fracture of the clavicle, and each had been treated by a method differing from that employed in the others. One had been treated with plaster-of-Paris, another with adhesive plaster, a third with an axillary pad and roller, etc. In each case overlapping of the fragments was present, and it was said to be an inevitable result. In the case in which the axillary pad had been used, the roller had been so tightly adjusted in the effort to employ the arm as a lever to hold the fragments in proper apposition, that paralysis of the arm had been produced as the result of pressure upon the nerves. All these cases had been treated outside of the hospital.

With regard to treatment of fracture of the clavicle, the remark was made that as yet nothing had been devised which would throw the shoulder back and retain it in that position. The nearest approach to success in that particular was secured by placing the patients upon the back, but it was almost absolutely impracticable to retain them in that position a sufficient length of time.

**INCOMPLETE FRACTURE OF THE CLAVICLE—EXCEPTIONAL SEAT OF THE FRACTURE.**

The fracture in this instance had occurred in the right clavicle of a child, at the junction of the outer and middle third. It belonged to the incomplete or "green-stick" variety. The seat of the fracture was that ordinarily occupied when the accident occurred in adults. It was therefore exceptional in the child, for with nearly the same uniformity this fracture, in the child, occurs in the middle portion of the bone. It was claimed by the visiting surgeon that provisional callus occurred only as an exception in adults, but that in the child it was the rule. In the case before us a node-like swelling was noticed by the mother the next day after the child received the injury. The bone was bent considerably, but it was said that the alignment would ultimately be restored and that the callus would disappear. Dressing was necessary only as a warning against accidents that might make the fracture complete.

**FRACTURE OF THE ACROMION PROCESS—INTERESTING BECAUSE OF ITS UNUSUAL SITUATION.**

There was slight motion and slight crepitus, but no displacement. The bone was fractured *outside* of the acromio-clavicular junction, and that unusual situation of the fracture gave the case its interest.

**DIASTASIS AT THE HEAD OF THE HUMERUS—FAILURE OF ALL EFFORTS AT REDUCTION.**

The accident had occurred at the shoulder of a young man about sixteen years of age. The upper convex surface of the extremity of the humerus could be distinctly seen and felt on the front aspect of the joint. A variety of methods had been employed for reduction, but unsuccessfully, and Dr. Moore's method was repeated in presence of the class. That also failed, but it was not regarded as a fair test for the method, for the reason that there had probably been some effusion between the detached parts.

**DISLOCATION OF THE HEAD OF THE HUMERUS UNDER THE CORACOID PROCESS—DIAGNOSTIC SYMPTOM OF DISLOCATION AT THE SHOULDER-JOINT—REDUCTION BY MANIPULATION.**

The case illustrated in a very marked manner the diagnostic symptom of dislocation at the shoulder-

joint. When the joint and its surroundings are normal, if the palm of the hand be placed over the opposite shoulder, like a saddle, the elbow can be brought in contact with the chest with perfect freedom. The same thing may be accomplished when a fracture has occurred in the neighborhood of the joint. When a dislocation, however, has taken place at this joint, and the palm of the hand upon the affected side is placed over the shoulder of the well side in the manner referred to, the elbow stands out from the body and cannot be brought in contact with the chest. This fact was illustrated in the case before us. The dislocation was reduced by manipulating in the following manner. The arm was extended until brought at a right angle with the long axis of the body, the fore-arm was flexed at right angle with the arm and then used as a lever to produce rotation forwards by turning the palm of the hand down and carrying it around until the head of the bone was thrown into the glenoid cavity.

**CONCUSSION OF THE BRAIN—REMARKABLE DURATION OF UNCONSCIOUSNESS—PECULIAR FACT REGARDING MEMORY.**

A male patient had fallen about fifteen feet, and had probably struck upon his head, as there was a contused wound there, and no wound upon any other part of the body. He was brought to the hospital, gave the usual symptoms of concussion of the brain, and remained in a state of unconsciousness *nine* days. At the end of that time his consciousness was entirely restored, and his intellect in the main seemed to be unimpaired, for he told his story in an intelligent manner. There was one noticeable fact relating to his memory, and it was said to be a peculiarity of such cases; namely, he had no recollection of anything that occurred upon the morning of the accident, nor of the day previous. His latest recollection was regarding an appointment made the second day before the occurrence of the accident. His treatment had consisted chiefly of rest in bed.

## Progress of Medical Science.

**CAN SYPHILIS BE CONVEYED BY THE MILK?—R. Voss** considers it proved by the following experiments that syphilis is as capable of being conveyed by the milk of syphilitic persons as by the blood. He injected a Pravaz syringe-full of milk from a syphilitic woman into each of three prostitutes. The mammary glands were entirely free from the disease, and the milk was obtained by pressing it out. One of those experimented on was already syphilitic, and the result nil. Nor was there any result on the second. In the third, who was not syphilitic, the injection was made on September 27th; an abscess formed, as in the others, and after it was healed a papular eruption showed itself round the site of the injection on November 3d. This was followed by more general manifestations, which yielded to inunctions.—*Petersb. Med. Wochenschr.*, 1876, No. 23; *Contr.-Bl. f. d. Med. Wiss.*, Oct. 28, 1876.

**THE ACTION OF Pilocarpium Meriaticum.**—Dr. Adolph Weber, of Darmstadt, has been testing an alkaloid prepared by Merck, from *Pernambuco jaborandi*, and called *pilocarpium meriaticum*. He finds that the subcutaneous injection of one c.c. of a two per cent. solution of the salt—which, by the way, is painless—is equivalent to an infusion of about seventy-five

grs. of jaborandi leaves in four ounces of water. Its first and most constant effect is an increased secretion of saliva, which sets in some five minutes after the injection and outlasts the sweating. This latter begins about five minutes later, and is often accompanied by a decided chilliness. With the dose mentioned it lasts about an hour on an average, if the patient is up; two or three hours if he stays in bed. There is at times a slight increase in the frequency of the pulse and in the temperature. There is but a slight and occasional feeling of weakness, while nausea or vomiting are infrequent. The last two points constitute a great advantage over the decoction of jaborandi. The contraction of the pupil begins late, but lasts on an average for twelve hours. When instilled into the eye, the maximum effect is reached in from twenty to thirty minutes and lasts three hours. Weber claims great advantages from the use of this salt in cases of turbidity of the vitreous after chronic iridochoroiditis; also in the treatment of a case of oedema of the lungs, following tracheotomy for croup.—*Centr.-Bl. f. d. Med. Wiss.*, Oct. 28, 1876.

**NEW METHOD OF TREATING URETERAL STRICTURES.**—At the meeting of the *Académie de Médecine* at Paris, on November 7th, M. C. Fort described a method of treating urethral strictures of small calibre, which he has employed for seven years with great success. He first passes a filiform bougie through the stricture and leaves it in position for twenty-four hours. The presence of the bougie excites a slight inflammation of the tissues that form the stricture, which softens them and renders them more extensible. The bougie is provided with a metallic cap, to which catheters of various sizes may be attached. At the end of twenty-four hours, a conical catheter, three millimetres in diameter at the largest part, is attached to the bougie, and pushed forward through the stricture, the guide keeping it in the proper direction. The catheter is then withdrawn until the metallic cap on the end of the bougie emerges from the meatus. The catheter is now detached from the bougie and replaced by another, which is five millimetres in diameter at its largest part. This is in turn made to traverse the stricture, then withdrawn, and replaced by a third catheter which measures seven millimetres in its largest diameter. The bougie during the passage of the catheters coils up in the bladder, where it can do no harm.

By this method even very tight and indurated strictures may be completely dilated at a single sitting. The guide removes all danger of making a false passage. The pain is so slight that anesthesia is unnecessary. The operation rarely causes any hemorrhage. During the seven years that M. C. Fort has employed this method, he has never known it to be followed by any complications except an occasional attack of urethral fever, which has always readily yielded to quinine. To prevent a relapse, a catheter must be passed at intervals for a long time.—*Gazette Médicale de Paris*, November 11, 1876.

**TREATMENT OF NEUROSES OF THE HEAD.**—At the séance of the *Académie de Médecine*, at Paris, on October 21st, Prof. Bitot, of Bordeaux, read a memoir on the efficacy of light cauterizations of the pharyngeal mucous membrane in the treatment of certain neuroses of the head with coincident amnesia, and on the probable role of the superior cervical ganglion in these cases. The following are his conclusions:

1. The head is the seat of certain nervous troubles, the precise localization of which is not as yet settled.
2. The cranial portion of the great sympathetic

must have some influence in the production of these disturbances.

3. It is rational in that case to assume that the superior cervical ganglion, which constitutes the principal centre of the sympathetic system in the head, is the point of origin of the nervous disturbance.

4. The anatomico-physiological importance of this ganglion, which is veritably the brain of the vegetative life of the head, must be borne in mind by the observer, whenever a neurosis of this region comes into question.

5. The observer must particularly bear in mind that this neuropathic condition will be rebellious to the ordinary methods of treatment.

6. The relations of this ganglion with the pharyngeal mucous membrane make the latter the point of election for the application of certain irritants that will act on the ganglion and its most distant branches.

7. The painting of this mucosa with the tincture of iodine has furnished remarkable results when the disturbances were essentially nervous. On the other hand, it had proved useless in the disturbances consecutive to apoplexy.

8. In many cases complicated with amnesia, the memory has been regained under this treatment.—*Gazette Médicale de Paris*, November 4, 1876.

**SPRAINS OF THE MEDIO-TARSAL ARTICULATION AND THEIR TREATMENT.**—The writers on surgery who have treated of sprains of the foot have usually only described one variety of sprain, viz., that of the ankle-joint, although the injury often affects the medio-tarsal joint, the articulation of Chopart. When this joint is injured, the patient is able after the accident to walk on level ground when the sole of the foot can be put down squarely; but, on the other hand, a very severe pain is caused by the slightest twist of the anterior part of the foot upon its posterior half. This pain can be easily excited by seizing the anterior part of the foot and twisting it on its antero-posterior axis. There are also tenderness on pressure over the medio-tarsal articulation, and ecchymosis and swelling of the dorsum of the foot. This variety of sprain, which is often too slight to prevent walking, may be neglected as it causes so little trouble, and then in certain predisposed subjects may lead to chronic arthritis and all its unpleasant consequences. When the sprain is marked, M. Terrillon recommends the employment of prolonged, methodical massage as soon as possible after the accident. The massage should be at first gentle, and be gradually made more energetic, and may be repeated in the more painful cases. A flannel bandage should then be snugly applied to the foot, and the patient recommended to walk around as soon as possible, notwithstanding the pain the first steps will cause him.—*Le Mouvement Médical*, October 14, 1876.

**TEMPERATURE OF THE FÆTUS IN THE UTERUS.**—Dr. Alexeeff, assistant to the obstetrical clinic in the University of Moscow, reports some observations on this subject, that confirm those of Wurster. In eight cases he has been able to take the fetal temperature during labor; in four of these cases the breech presented, and the rectal temperature of the child was taken; in the other four cases the face presented, and the temperature was taken under the tongue. He has constantly found the fetal temperature higher than that of the vagina of the mother.—*Lyon Medical*, October 29th.

**EFFUSION OF BLOOD INTO THE KNEE JOINT.**—At a recent meeting of the *Société de Chirurgie* of Paris, M. Nicaise presented to the Society a knee-joint removed from the body of a man sixty-six years of age, who had been injured in August, 1875, by a fall on

the left knee. A violent contusion resulted from the fall, which forced the patient to enter a hospital. He was under almost constant treatment in various hospitals until his death on October 31, 1876. At the autopsy the knee-joint was opened by a curved incision above the patella, and the cavity of the joint was found to be filled with a clot of blood that was attached to the posterior surface of the patella and to the condyles of the femur by rather firm, glutinous adhesions. It was also adherent to the synovial membrane. At the point of contact of the femur and tibia, small, flattened lamellæ of fibrin were found. The clot was fibrous, and colored by the hæmatine, just as a recent clot would be. The other lesions found at the autopsy were not described. M. Nicaise thought the specimen interesting on account of the length of time (14 months) that the clot had remained intact in the cavity of the joint.

M. Marc Sée did not believe that the effusion took place at the time of the accident; he thought that the joint had been affected for a long time with fibro-plastic arthritis, and the sanguineous effusion was of recent date. M. Verneuil took the same view, and maintained that it was impossible for effused blood to remain so long unchanged, even in a closed cavity. Microscopical examination, however, was necessary to settle the question. MM. Trélat and Léon le Fort dissented from this view, and insisted that clots of blood sometimes remain for years unchanged. The former referred for illustrations to the cases reported by Morel Lavallée, and the latter pointed to the fact that in an aneurismal sac that is perfectly cut off from the current of the blood, a clot is not unfrequently found at the end of two or three years or more, presenting exactly the same appearance as the specimen presented by M. Nicaise.—*La France Médicale*, November 18th.

DISLOCATION BACKWARD OF THE ACROMIAL END OF THE CLAVICLE.—In an instance of this somewhat rare form of dislocation observed by M. Nicaise, at the Hôpital St. Louis, Paris, an attempt was made to effect reduction under chloroform, but without success; the arm was accordingly put in a sling. Some experiments were then made upon the dead body, to determine the mode of production of this form of luxation. Section of the acromio-clavicular ligament did not allow of it, but when the trapezoid was cut and the conoid left intact, the desired displacement was effected; it was accordingly inferred that rupture of the trapezoid ligament is necessary in such dislocations.—*Lancet*, Oct. 14, 1876.

THE POISONOUS ACTION OF WATER HEMLOCK (*CICUTA VIROSA*) AND ITS CONSEQUENCES.—Prof. Boehm, of Dorpat, as the result of experimental investigations upon *cicuta virosa*, has obtained a substance possessing the peculiar properties of the plant, which he names *cicutaria*. In its action upon the animal economy, it is identical with the salts of baryta and with picrotoxin. He found that cicutoxin was absorbed by the stomach slowly, and that the smell was strong when the bodies of poisoned animals were opened. He therefore suggests that, in medico-legal cases where it is suspected, the stomach and intestines should be washed with ether and experiments made with the extract obtained. In the case of frogs, it was ascertained that the hemispheres had nothing to do with the development of the *cicuta* spasms. Nor does the cerebellum share in them. If a section is made through the spinal cord below the calamus scriptorius, the parts supplied by the spinal nerves given off below the section are paralyzed, while their

reflex irritability remains. There are the characteristic spasmodic movements of the head, neck and chest, and the peculiar cry. The latter is explained by the excess of inspiratory over expiratory action on filling the lungs. Then, when the spasmodic seizure sets in, the abdominal muscles contracting, force the air out again through the larynx, which is itself spasmodically narrowed. In mammalia, after ingestion of the poison, there is a period of repose, lasting from fifteen to thirty minutes. Then the animal grows uneasy, and is soon attacked by the characteristic violent tetanic spasms. The immediate cause of death is deficient respiration. When given by the mouth, about three-quarters of a grain of cicutoxin to every two pounds in weight will be a fatal dose for a cat; but more will be needed for a dog. The action of the poison is exerted upon the medulla oblongata.—*Arch. f. Exper. Pathol. u. Pharm.*, V., p. 279, 1875; *Schmid's Jahrb.*, 1876, Bd. 171, No. 9.

THE REAL ORIGIN OF THE HYPO-GLOSSAL NERVE.—In a recent number of the *Journal de l'Anatomie M.* Duval has a memoir on the real origin of the cranial nerves having motor functions, the investigations upon which he forms his conclusions having been made upon sections hardened by immersion in bichromate of potassium and chromic acid. He describes the now well-known course that the hypo-glossal takes, tracing it inwards as it enters the fissure between the olivary body and the anterior pyramid on either side, and so in its course to the hypo-glossal nucleus, one of which is situated on each side at the posterior extremity of the raphe of the bulb. He finds that these *afferent* fibres do not decussate. The thickness of the nucleus is about an eighth of an inch, and in man it may be seen by the naked eye beneath the delicate ependyma and ciliated epithelium of the fourth ventricle. The nerve cells are of two kinds; those that resemble the cells in the anterior cornua of the medulla, mostly large and multipolar, and others of much smaller size. But the most interesting observation seems to be that there are also *afferent* fibres, as he calls them, which, proceeding from the encephalic centres, and running in the antero-lateral columns of the bulb, enter the raphe and then decussate, passing into the hypo-glossal nucleus of the opposite side and passing into the nerve-cells of the smaller size. It is thought accordingly that this microscopical observation will explain those cases of paralysis of one side of the tongue that are caused by lesions of the cerebral hemisphere of the opposite side. The decussation is therefore in the *afferent* fibres, and not, as Koelliker and others have maintained, in the *afferent* ones.—*Lancet*, November 4, 1876.

ON THE RADICAL CURE OF HERNIA.—Dr. Julius F. Miner, of the Buffalo General Hospital, expresses himself succinctly and decidedly in regard to this operation. He says, notwithstanding the reports of successful cases, his opinion is still that in femoral hernia the operation is too dangerous to be justifiable; in umbilical hernia the congenital form usually disappears in after-life, and the acquired form occurs generally in elderly stout people, who are not fit subjects for surgical operation. The operation in practice is confined to persons of the male sex, but it ought never to be performed except upon patients "who have been properly informed of its dangers, and who deliberately choose to incur them."—*Archives of Clinical Surgery*, December, 1876.

MAUNDER ON EXCISION OF THE HIP JOINT.—In some clinical remarks made at the London Hospital, at an

operation for hip-joint disease. Mr. Maunder said that a very large majority of patients with this disease recover without an operation. In about a dozen cases then under his care the only chance for life in two, and for recovery without extreme deformity in one, was excision. He stated that there are two different processes of disorganization in a joint, one with and one without suppuration. As the gelatinous form of the disease may run its course without suppuration, surgeons should be encouraged to seek for recovery by fibrous ankylosis, and should not be hasty in condemning such a joint to excision, or the limb perhaps to amputation. Four cases are given in which he excised in June last; in two there was such free suppuration as to threaten life; in the third, deformity was great, disorganization of the joint complete, and ankylosis had occurred in a faulty position; in the fourth, there was a right angular deformity with suppuration. The upper end of the bone was then removed without splintering, and a sequestrum was extracted. This sequestrum had been the cause of suppuration for seven years. All of the cases did well.—*Lancet*, Oct. 14, 1876.

**DISEASE OF THE STERNO-CLAVICULAR ARTICULATION**—Mr. Hamerton, of the Lambeth Infirmary, has had under his care three cases of this affection. In all of them, painful swellings occurred at the articulation, pus formed, and death of the bone ensued. In two of the instances death occurred; in one from phthisis, and in the other from pyæmia, it is alleged. In the third case the bone was resected and great improvement followed. M. H. regards the disease as imperfectly understood, and the cause of the disease obscure, inasmuch as the history of neither injury, syphilis, gout, or rheumatism could be elicited. Dr. Gross, of this country, however, has alluded to somewhat similar cases under the title of tuberculoses of the sterno-clavicular articulation, and the fact that in Mr. Maunder's cases one of the patients died of phthisis and two had been troubled with cough, would suggest that the disease may also have been tubercular in them.—*Lancet*, Nov. 25, 1876.

**THE ANTISEPTIC METHOD.**—The following succinct statement of the way in which the antiseptic method may be carried out is from the advanced sheets of a *Manual of Operative Surgery*, by Dr. Stephen Smith. There should be at hand: 1. A vessel containing carbolic acid dissolved in water (1-40), for the immersing of the hands of the operator, the sponges and instruments used in the wound. 2. A steam-spray apparatus, capable of giving a cloud of vapor; make the solution of carbolic acid to be atomized 1 to 30, which diluted by the steam will give a 1 to 40 spray. 3. Antiseptic gauze, open cotton cloth impregnated with carbolic acid 1 part, common resin 5 parts, and paraffine 7 parts. 4. Mackintosh (fine cotton cloth with a thin layer of caoutchouc on one side, known in the shops as hat-lining;) gutta-percha tissue of good quality will also answer, but is liable to wear into holes. 5. Drainage-tubes (India-rubber, with a silk ligature attached). 6. Oiled-silk protective (oiled-silk coated on both sides with copal varnish, and afterwards brushed over with dextrine); when the copal varnish has dried, a mixture of one part of dextrine, two parts of starch, and sixteen parts of carbolic acid is brushed over; the acid soon evaporates. Common oiled-silk, smeared with the oily solution, will answer the purpose pretty well, especially if used in two layers. 7. Carbolyzed catgut ligatures.

If the wound is accidental first wash the cut surface thoroughly with a saturated watery solution (1-

20); if the wound is made by the surgeon: (1) shave the part in order that the antiseptic may not be prevented from acting upon the skin; (2) wash the part with a watery solution (1-20), to purify the skin; (3) direct the spray upon the part, and maintain its action and position during the entire operation and dressing without a moment's interval; (4) immerse the hands, instruments, and sponges in the 1-40 solution before operating, and at every interval of the operation when they are not enveloped by the spray; (5) tie all vessels with antiseptic catgut and cut the ligatures at the knot; (6) place the drainage-tube or tubes so deeply in the wounds as to drain all accumulating fluids; if the tube enters obliquely, cut the outer extremity obliquely; lay the retaining threads on the surface; (7) if the wound is to be closed, as after amputation, use carbolyzed silk for sutures; (8) if strapping is required, common adhesive plaster may be rendered antiseptic by dipping it for a second or two in a watery solution of the acid, and it is most convenient to have the solution hot; the ends should be overlapped by the gauze; (9) apply to the cicatrizing part a layer of the oiled-silk protective dipped in the watery solution, and having a hole for the drainage-tube; (10) apply eight layers of the gauze of such size as to cover all the wound and the adjacent parts; dip the first layer in the solution; between the two last layers place a piece of mackintosh of smaller size than the layers of gauze; apply the last layer so as to cover in completely the mackintosh; (11) retain the dressings by bandages of the antiseptic gauze. Inspect the wound on the following day, and change the dressing only in case the discharge is liable to extend beyond the edge of the folded gauze; during the subsequent progress of the case leave the gauze undisturbed for periods varying from two days to a week, according to the diminution of the effusion. In re-dressing, continue the spray uninterruptedly on the part; while the bandage is being cut or removed, the patient or an assistant keeps his hand over the site of the wound, to prevent the dressing from rising *en masse*, and pumping in septic air; in raising the folded gauze take care that the spray passes into the angle between it and the skin; remove the drainage tubes, cleanse them in the carbolic-acid solution, and before reintroducing them cut off such portions as the granulations in the wound render necessary to bring the external extremity flush with the surface of the skin; lay aside the gauze which is soaked, but use the mackintosh again after cleaning it with carbolic-acid solution.—*Boston Med. & Surg. Journal*, Dec. 7, 1876.

**THE HISTOLOGY OF SHEEP-POX.**—At a meeting of the Royal Society in June last Dr. Creighton, who has recently been employed in researches relative to cancer, showed that appearances similar to those that Dr. Klein had depicted as belonging peculiarly to the virus of ovine-pox, and supposed to be parasitic, were obtained abundantly in healthy tissue. In a note, read at the same time, Dr. Klein accepted the explanation. It was said that there was large justification for regarding the albuminous coagula, for such they were, as specific organisms. The filamentous, branched and knotted appearance which they gave was very like that of an organic growth. In many instances also they met and formed a network. The microphytic theory in relation to ovine-pox may therefore be regarded as disposed of for the present.

**SPINA-BIFIDA TREATED BY THE IODO-GLYCERINE SOLUTION.**—Professor Morton, of Glasgow, adds another successful instance of injecting the tumor in

spina-bifida with the iodo-glycerine solution. The malformation was in the lumbar region, the sac the size of an ordinary peach, and not very full. The operation was done a few weeks after birth, the method being puncture and injection of about half a drachm of the solution; very little of the serous fluid was permitted to escape. Collodion was applied to the opening, over which was also placed a square inch of lint dipped in collodion, so that the wound was effectually closed. As shrinkage of the tumor was slower than anticipated, another puncture was made twelve days after the first operation, though in this case only a few drops were injected. A month later it was reported that the child was doing well, and the tumor had shrunk; and though the skin covering the centre was bluish for the breadth of a shilling, it was firm to the touch. This case is said to have been the fourteenth in which this treatment has been used, and eleven of them have been successful. Prof. Morton has found it uniformly successful in all the lumbar cases he has treated.—*Lancet*, Dec. 2, 1876.

**A DOUBLE AUTOSITE.**—An interesting case of double monstrosity is reported by Dr. Berjoan, of Cairo. The parents of the monster are healthy Bedouins; the mother, after giving birth successively to five children, who are all living and healthy, was delivered of the monster on the 6th of last August. It possesses two heads, two thoracic cavities, each containing two lungs and a heart normally situated, with a single abdomen and a single umbilicus. It possesses also four well-formed arms and three legs, two of which are slender but well formed, while the third is rudimentary. The foot of this last leg is deformed. At the base of the abdomen there is a small caudal enlargement, presenting at each end a small, round opening. One of these openings gives exit to the feces, and Dr. Berjoan thinks that the other is probably the orifice of a vulvo-uterine canal. The parents would not allow an exhaustive examination to be made. The exploration, however, incomplete as it was, showed that the respiratory and circulatory functions in the two trunks are entirely independent, and that the two individuals, after performing separately all the acts of nutritive life, find a common existence in the abdomen and in the excretion of the feces and the urine. The monstrosity was twenty-one days old when seen by Dr. Berjoan, and the two infants were then in the enjoyment of perfect health. They nursed, cried, and slept perfectly well, independently of one another.—*Le Mouvement Médical*, November 4th.

**SEALING OF COMPOUND FRACTURES WITH THE COMPOUND TINCTURE OF BENZOIN.**—Mr. Bryant, of Guy's Hospital, has been treating fourteen consecutive cases of compound fracture by closing the wound as soon as possible after the accident, with lint saturated with the compound tincture of benzoïn. The results obtained have been almost uniformly satisfactory. In one case where the injury was produced by the kick of a horse, the fracture was at the junction of the middle and lower third of the limb. A piece of bone projected through the lacerated wound, and there was much contusion. The dresser, Mr. Peacock, at once reduced the fracture, and closed the wound with several pieces of lint saturated with the compound tincture of benzoïn, and then swung the limb upon suitable splints. No pain or constitutional disturbance followed. When the lint was removed on the 25th day, the wound had completely healed and the fracture was united. Three other consecutive cases are given, in all of which good results followed. In the second case, the dressing re-

mained undisturbed for twenty-seven days, and on being removed the wound was healed and the bones were consolidated. About three weeks later he left the hospital with a good leg.

The third and fourth cases are much of the same character, in the one instance the dressing remaining in place twenty-six days, and in the other sixteen.—*Lancet*, Nov. 25, 1876.

**URETHRAL AND VESICAL MANIFESTATIONS OF RHEUMATISM.**—In a paper on this subject, M. Guillaud maintained that rheumatism may excite urethral discharges, inflammation of the neck of the bladder, and spasm of the bladder. In 1866, M. Peter asserted that the facility with which hemorrhagia is produced in some persons, and the repetition of the same affection in others, depend upon the rheumatic diathesis. In these cases the affection is a *rheumatismal hemorrhagia*, and not a hemorrhagic rheumatism. M. Guillaud stated, in the first place, that urethritis in rheumatic individuals has a great tendency to run a protracted course, and often yields only to the alkaline treatment. Then he cites well-authenticated cases which show the development of urethritis in rheumatic patients, when there was no possibility of contagion. Sometimes the rheumatic manifestations showed themselves first in the urethra, sometimes first in the joints. In the latter cases it is necessary to admit that the urethral mucosa is attacked secondarily by the rheumatic poison, just as all the other tissues of the body may be secondarily attacked. These facts have an important bearing on the question of treatment, for they prove that many cases of hemorrhagia whose long duration has exhausted the patience of both patients and physicians, may be cured by discarding local applications and treating the diathesis alone. All that has been said here of the mucous membrane of the urethra applies also to that of the bladder.

To sum up, a gonorrhœa, just as any traumatism or any disturbance of the organism, may awake a slumbering rheumatic diathesis, and lead to fresh attacks of the joints; on the other hand, rheumatism may, independently of any other cause, produce urethritis, cystitis, or muscular contractions of the bladder; it may affect the mucous membrane and muscles of the genitals, in the same way as it affects the mucous membrane of the pharynx and the muscles of the body in general.—*La Tribune Médicale*, November 12th.

**ACUTE IDIOPATHIC PERITONITIS IN CHILDREN.**—The following are the conclusions of a paper on this subject by M. Gaudereux:

A variety of peritonitis is met with in children, which may be called acute, essential, or idiopathic peritonitis. This peritonitis is usually general, but in some few cases is circumscribed, a more or less extensive portion of the peritoneum being involved.

It affects little girls much more frequently than boys, but is not exclusively confined to them.

It is excited by exposure to cold, or by excessive muscular action, and is especially prone to attack children between five and twelve years of age.

It may terminate in suppuration, but although the case is then very grave, it is not entirely hopeless. In fact, the pus may make its way out through the umbilical cicatrix, and in that case recovery may be looked for. It is evident from this, that suppurative peritonitis is less dangerous in the child than in the adult.

Phlegmon of the abdominal walls, or subperitoneal phlegmon, is the affection with which it is most likely to be confounded.—*La Tribune Médicale*, November 12th.

# THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, January 13, 1877.

## CHLOROFORM AND DENTISTRY.

THE mere announcement of another death from chloroform has of late become so frequent that, unless some new pathological changes are noted in connection with it, or some important lesson can be learned in regard to the prevention of an accident which is always deplorable, we are too apt to pass it over as a simple fact, which may possibly be of some value to the statistician. The association of the accident with the mere extraction of a tooth does not tend to raise it above the level of tame and commonplace occurrences. In fact, we have become so accustomed to look upon the two circumstances in the relation of cause and effect, that we cease to wonder at it, and our appetite pales at promise of a recital of details.

The recent death, at Rahway, N. J., is, however, of a character which may prove of more than ordinary interest in connection with some of the circumstances attending it. At least, it can do no harm to remind ourselves of the oft-repeated warnings concerning the danger of chloroform at a time when such an example of their significance is still fresh.

In another column we present a full account of the case. The manner in which the accident was produced, and the culpable want of care in preventing it, are matters which not only throw the most serious reflections upon the judgment of the dentist, but lay him open to the charge of actual criminality. There can be no doubt that death was due to the use of chloroform in this case; it is equally certain that chloroform should not have been administered at all; and it is also apparent that the person who assumed the responsibility of the administration was thoroughly incompetent.

In regard to the use of chloroform in dentistry there is but one opinion, namely, that it is always dangerous. As a general rule, it should never be administered at all for purposes of tooth extraction. In the present

state of professional opinion upon the subject, the dentist who chooses to administer it even in a special case, assumes a responsibility of which he should not be ignorant. So great is the prejudice against this anæsthetic among leading dentists, that many will not allow it to be administered in their offices, even when the direct professional responsibility is assumed by an experienced physician.

Although the fact cannot be very well explained, chloroform has taken more victims from the dentist's chair than from any other place. Indeed, it has gained its reputation as a dangerous article more in connection with simple tooth-drawing than with any other operation, however grave or formidable. A very good reason for the liability to accidents is the erect position of the body of the patient while in the operating chair. Taking this into account, authorities are unanimous in advising that chloroform should never be given except the patient is recumbent.

In the Rahway case the dentist not only defiantly violated the rule never to administer the anæsthetic for tooth-drawing, but he neglected all the usual precautions to guard against an accident. No surgeon cares to assume the responsibility of giving chloroform unless he knows that the stomach of the patient is empty, that the circulatory apparatus is in good condition, and the lungs free from disease. A previous inquiry into these conditions is as much a part of the administration of any anæsthetic as is the placing of the napkin to the nose. It appears in the case before us that all these preliminaries were neglected. The patient came into the office immediately after having eaten a hearty meal, and, without any questions being asked, was at once placed in the operating chair. There was no loosening of waistband or shirt-collar, no examination of the chest—in fact, nothing was done except to order the little fellow to take long and deep inspirations, while the napkin was held closely against the nose. The result could have been easily foreseen. The overwhelming effects of rapid anæsthesia and the crowding impediment of a full stomach, in the most unfavorable of all positions of the body, did not invite death in vain. It would seem that the actual extraction of the tooth was done when the patient was already dead, or, at least, *in articulo mortis*.

The examination of the bodies of patients dying from the effects of chloroform have not thus far given us any satisfactory pathological explanation. The lesions have varied with each individual case, and have given rise to as many different theories. The careful and thorough examination of the body of the victim of the Rahway tragedy still leaves the question an open one. From a study of the pathological appearances, and from a personal inspection of all the organs examined, the most reasonable theory which offers itself to our mind, is that death occurred as the result of a direct operation of chloroform upon the nerve-

centres, inducing paralysis of the heart. Although there were marked evidences of asphyxia, they were not complete enough to impress those who were present with primary importance in regard to the cause of death. We are aware that in cases of death by paralysis of the heart, both ventricles are usually filled with blood, and that in asphyxia only the right side of the heart is in that condition; but the circumstances of the case may, in the absence of what appears to be a better explanation, render the theory of asthenia still reasonably tenable. At the time of death, both cavities of the heart may have been distended, and the subsequent and prolonged application of galvanism to the precordia may have induced a sufficient amount of post-mortem contraction of the heart-muscle to have emptied the cavities. The left ventricle being, for obvious reasons, the one most strongly acted upon, might satisfactorily account for its being entirely empty while the right side still contained some blood. Or, if we wished to carry our theorizing further, we might suppose that both ventricles were entirely emptied after death, and that the dark fluid in the right ventricle was the result of regurgitation. It may be, however, that both asphyxia and asthenia operated together in producing the effect; but the precedence which should be given to either involves the discussion of some questions for which, in the present state of pathology regarding deaths from chloroform, we are not yet prepared.

#### THE RELATION OF SURGEONS TO DUELLISTS.

THE ridiculous duel, the account of which has so recently engaged the attention of the public, has some interest to the profession, in regard to surgical attendance. Generally speaking, a surgeon's business is understood to confine itself to the care of his patient. He is, in fact, a non-combatant, and does not pretend to assume any responsibility as to the cause of any accidents, in peace or in war, which render his services necessary. In the legitimate exercise of his functions he is always understood to be a law-abiding citizen, ready and willing to give assistance to any one who may need it. The attendance upon a duel, however, involving as it does an understanding that a flagrant violation of law is contemplated—that a deliberate murder may be committed—throws upon the surgeon so engaged an amount of responsibility which, in justice to his brethren, he has no right to assume. In fact, his consent to act in this capacity not only involves a sacrifice of good judgment, loyal citizenship, and professional respect, but in the eyes of the public and the profession he degrades himself to the level of a tacit abettor to a crime. In view of our opinion upon the subject, it is with pain that we record the fact that a respected member of the profession of this city so far forgot his personal and professional obligations as to give any countenance to the proceeding.

## Reports of Societies.

### NEW YORK PATHOLOGICAL SOCIETY.

*Stated Meeting, Dec. 12, 1876.*

DR. C. K. BRIDGON, PRESIDENT, IN THE CHAIR.

DR. HEITZMANN reported the case of polypus of the rectum, presented by Dr. Lewis Smith, to be adenomatous in character.

#### THE SAND-WORM AS A STOMACH PARASITE.

DR. FLINT presented the following report from Dr. Dalton, in regard to the specimen of worm presented at a previous meeting, which was reported to have been discharged from the mouth of a female:

NEW YORK, Nov. 23, 1876.

DEAR DOCTOR:—The specimens which you gave me are fragments of a *vermis*, an articulate animal belonging to the class annelida. It is not a parasite, but lives under the sand of sea-beaches, below high-water mark. Its common name is *sand-worm*, and it is used by the fishermen as bait for bass and tomcod. I send you an entire specimen, and also a few living worms in moist sand, which I purchased at a shop in Eleventh avenue, at the rate of one dollar per hundred. You need not be at the trouble of returning me the specimen.

Yours truly,

J. C. DALTON.

#### PENTASTOMA CONSTRICTUM.

DR. FLINT also exhibited a specimen of pentastoma constrictum, which had been sent to him by Dr. M. M. Campbell, of Albany, Gentry Co., Mo., who furnished the following history:

J. R. Robinson, aged 36 years, farmer by occupation, and served three years in the army during the war, applied to me in September last for examination, with the following story: Said that he had been very bad with an acute attack of pleurisy or pneumonia in March or April last (when I was at Bellevue Hospital Medical College, N. Y.); the physician who attended him said it was pneumonia, and that he was left weak and reduced very much in flesh, and came to me for treatment. I examined him and found a large vomica in the apex of the left lung, and dulness over a large area. The night before he came to me he said something had burst in that lung, and that over a quart of offensive matter run out of his mouth and nearly choked him, and since then something has continued to break and discharge about once every one or two weeks, and always at night—near morning. Since I saw him, in September, he has lost flesh rapidly, and there are now two large cavities in the lung and considerable effusion into the pericardium, while that lung is very tender on percussion. The liver is considerably enlarged (very much), and the bowels seem bloated all the time, and have not decreased in size with the rest of the body, and when stripped he looks like an emaciated child with bloated belly; he is sallow, his appetite is poor.

About a month ago he commenced coughing or vomiting up these parasites, and for ten days he ate nothing and was very weak; he said that they gagged him when coughing, and my presumption is that they came from the large cavity in the apex of the left lung, but I feel sure that his liver is also full of them, for it is much enlarged and very tender on percussion. Altogether he has coughed up from 75 to 100 of them, and they would crawl around the floor like a

naggot, and live for ten days in a bottle. They also stand freezing, for during the late cold snap, when he spat them upon the floor during the night, and the mucus and matter froze on the floor, when the fire was kindled in his room in the morning and the spittle thawed, they would then crawl around the floor. The sound of the gurgling in his lung has a distinct metallic tinkle, only finer, more resembling the tinkling of china-ware. I will send you the specimen securely bottled, to-morrow, to Bellevue Hospital Medical College, and I think it very probable that I will soon obtain more; and if a post-mortem can be obtained after a time, I will try hard to get permission to examine the diseased organs.

Following the presentation of the case, Dr. Flint read several extracts from Aitken's Practice, describing the parasite in question in connection with an account of the case of Private Isaac Newton (vide Aitken, vol. i., 194).

DR. E. MASON exhibited a boy, aged seven years, upon whom he had performed the operation of excision of the internal scaphoid and middle cuneiform bones, with a portion of the metatarsal bone of the great toe of the left foot. There was good motion in the ankle-joint, the wound was healed, and there was but slight tenderness on pressure. The following is the history of the case:

Dannie Lunaham, aged seven; United States; admitted to Bellevue Hospital Sept. 12, 1876. Previous history presents nothing of importance. No family cachectic or syphilitic taint. The injury appears to be ascribed to the foot having been caught and bruised by a shutting door. For three weeks after the patient scarcely complained, and was able to run about as usual. The first appearance of trouble was a small vesicle below the instep, which was pricked. A few days after erysipelas of the foot and leg set in, and patient was sent to Bellevue Hospital. The foot at this time was swollen and very painful, with a large suppurating opening on the inner side of the foot, corresponding to the internal cuneiform bone, through which the probe could be made to pass in every direction under the skin. No necrosed bone was made out. Treated with lead and opium. Sept. 20th.—The erysipelas has disappeared, and patient removed from pavilion to ward. Sept. 26th.—Other abscesses have shown themselves on different parts of the foot, and all communicating with each other. Was seen by several of the visiting surgeons. No necrosed bone can with certainty be made out, though the general appearance indicates pretty conclusively that dead bone is present.

27th.—*Operation.*—Under ether, dead bone was detected. At the clinique to-day Dr. Mason enlarged the opening over the internal cuneiform, and removed the scaphoid and internal and middle cuneiform, with the head of the metatarsal bone of great toe. A seton drawn through the incision and an opening over external cuneiform; no hemorrhage. 28th.—Foot and leg enclosed in an immovable plaster-of-Paris splint, with fenestra over arch of foot. Oct. 11th.—Always irrigated with carbolic acid water and dressed with balsam and picked lint. Oct. 30th.—Foot doing very well; same dressing. Nov. 15th.—Wound nearly closed. Nov. 21st.—Silicate soda splint applied; wounds finally closed. He is now able, when splint is removed, to place his foot firmly on the floor without pain. The color about the old wound is still somewhat bluish, but the cicatrix is firm.

#### EXSECTION OF HIP.

DR. SAYRE presented the following cases: R. M. B.

Patter, of Newport, R. I., aged seven; of healthy parents, and always an active, healthy child until four and a half years of age, when he was thrown from his hobby-horse, striking on his left hip, causing intense pain, which was followed by an acute inflammation of the hip-joint.

He was blistered repeatedly for eighteen months, and under the constant influence of bichloride mercury and bark; but *no extension was made to the limb.*

Abscesses formed, which opened near the pubis and on the outer part of the thigh, which discharged profusely, and the limb became strongly adducted and flexed.

He was sent to me by Dr. Sands in October, 1875, and by extension and proper treatment was so much relieved that for some months hopes were entertained that he might recover without excision. But the discharge continuing so profuse, and the probe detecting so large a mass of dead bone, that by the advice of Dr. Alfred C. Post, who saw him in consultation with me on the 20th of November, 1876, I performed excision on the 23d of November, 1876.

The bone was sawed off just at the trochanter minor. The head and most of the neck were absorbed, and the acetabulum perforated.

The operation has been performed three weeks, during which time there has not been as much discharge as there was in one day before the operation, and he is improving rapidly.

Henry Herman, San Francisco, Cal., aged six years. Father very strong and healthy; mother delicate. Child always healthy, but not very strong. Two years since fell over a chair, and complained very much at the time of pain in his left hip. Was seen by several physicians, who thought the trouble was rheumatic. Was rubbed with liniments, etc., for six months.

An abscess formed, which was opened about five inches below trochanter major, and has continued to discharge profusely ever since.

He is now much wasted, has hectic, and is failing rapidly. Excised hip at Bellevue Hospital, Dec. 13, 1876. Femur sawed off just below trochanter minor. Head and portion of neck absorbed, and acetabulum perforated.

#### NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, December 21st, 1876.*

DR. S. S. PURPLE, PRESIDENT, IN THE CHAIR.

REPORT UPON YELLOW FEVER AS IT OCCURRED IN SAVANNAH, GA., 1876.

DR. OCTAVIUS A. WHITE read a concise and interesting report, which embraced the results of his observations made while rendering volunteer medical service among the people of that city.

"Epidemics are nature's protests against the violation of her sanitary laws."

It was maintained that the portability of yellow fever germs had never been disproved; that experience had proved that cities extremely liable to its visitation, could enjoy an immunity from it by a rigid enforcement of quarantine; and that the germs of the specific form of the disease had, without exception, been imported to this country when it had made its appearance among us. In the present instance, its ingress was traced directly to vessels which had lately arrived from the West Indies.

#### CONDITIONS FAVORING THE EPIDEMIC.

The city of Savannah was so situated that its drainage was defective, and a great deal of the rain-fall

was obliged to pass off by evaporation and absorption, and it was surrounded on every side by vast tracts which required unremitting attention to prevent them from lapsing into septic sources of miasmatic emanations. The city was surrounded by such local influences as would at any time during the summer permit of the development of yellow fever, if the specific germ of the disease was indigenous; but it had often escaped this pestilence, while in a near city it had raged with unabated fury.

By some, Savannah had been placed in the so-called yellow-fever zone; but a critical review of the health record of the city, it was believed, established the fact that no other urban locality on the Atlantic coast enjoyed a superior reputation for general salubrity. To-day the city presented an unsolved problem to every disbeliever in the exotic origin of yellow fever in this country.

Dr. WHITE admitted that the conditions were present favorable for the development and spread of the disease when the germs had been transported thither, but he was not prepared to concede, with the light of the experience he had, that the city was in a zone capable of generating independently the specific poison upon which such an epidemic depended.

The same was said with reference to Charleston and other cities lying within a latitude liable to high range of temperature during three months of the year. It was believed that the experience had, in the season of 1876, established more firmly the theory of the exotic origin of the disease; and the history of no epidemic in this country seemed very clear, without the inevitable mention of a ship from some infected port.

During the early spring and summer of 1876, all the conditions and influences within and surrounding Savannah seemed to be favorable to the development of miasmatic diseases to an extraordinary degree. The average temperature for the month of June was 80.56° F.; the rain-fall, 18.80 inches; and the total number of clear days, 14.

For the month of July the mean temperature was 84.5° F.; rain-fall, 6.11 inches. The direction of the prevailing wind for both these months was southwest, and from over an undoubted malarial region.

There was no marked abatement in the heat during the month of August, as the mean temperature was 84.1° F. The rain-fall was 6.88 inches; the prevailing wind from the south.

The weather favored the dissemination of malarial germs, and the continued calms by night and day permitted their accumulation and concentration.

On driving through the streets of the city, nothing inimical to health presented itself; but it was manifest, upon close inspection, that numerous neglected privy-vaults nightly tainted the air with toxic exhalations. Besides those, there were what were called "dry wells," which were nothing more nor less than receptacles for human excreta; and close to the city limits were the dumping grounds of the scavengers; and, in addition, there was the Bilbo Canal, teeming, as did its tributaries, with putrescent refuse. The wide, stretching netherlands had, from neglect, been exposed to frequent overflow and saturation. About three fourths of a mile from the eastern portion of the city was a wharf which was the constant recipient of relays of blue clay from the coast of Cuba, in the immediate neighborhood of Havana.

Such a combination of favoring conditions and circumstances could hardly fail to create an epidemic.

#### FACTORS OF THE EPIDEMIC.

The epidemic, therefore, which prevailed at Savan-

nah during the season of 1876, was the combined product of three factors: 1. oöchlesis; 2. miasma; 3. the specific germ principle of yellow fever. Those factors gave rise to a disease that prevailed pandemically, and certain persons had a second attack, which, in some instances, proved fatal.

When Dr. White arrived at Savannah the pandemic was at its height. The general character of the disease reminded him that he had to deal with the form of affection described by Aitken under the head of "malarious yellow fever."

Upon the announcement that yellow fever was prevailing in the city, a considerable number of the residents went into the healthy sections of the adjacent country, and from there continued to visit the city daily and transact business, being careful to avoid the affected districts after sundown; and, without other precaution, it was said that they escaped the disease.

#### MODE OF INVASION AND SYMPTOMS.

Although the disease had its origin in the three factors mentioned, the mode of its invasion did not differ in any material respect from that so often described in less marked epidemics. The accession was rarely without premonition; giddiness, loss of appetite, tendency to sweat upon slight exertion, and flatulence were the common premonitory symptoms. The small hours of the day and night marked the period of onset. Every case began with a chill more or less marked; scorching fever immediately followed, bearing, however, no harmonious relation to the chill. The stomach was generally the first organ to sympathize, and distress with nausea, and sometimes vomiting, occurred. The suffering in the head, commonly limited to the brow, was not unfrequently referred to the course of the longitudinal sinus. But few cases presented delirium, though the countenance of each patient wore a distressed aspect; the face was flushed and turgid; the eyes were watery, heavy, and injected, and there was often tenderness to the touch, with intolerance of light; the respiration was hurried and often interrupted by sighs. Epistaxis occasionally occurred, to the great relief of symptoms; but the issue of the case invariably showed that such loss of blood was not favorably borne. Of all the torturing symptoms the patient was called upon to endure, spinal aching was the most intolerable. All the early symptoms appeared to result from a state of venous repletion. That peculiar condition formed a characteristic and enduring complication throughout every stage, quite up to convalescence, and accounted for many of the dangerous determinations which persistently threatened and retarded convalescence and ushered in fatal cases.

The tongue was usually moist, pale, swollen, and indented. The development of gastric irritability was foreshadowed, not by preternatural redness about the tips or edges, with coating, as often as by a marked tendency to dryness and pallor.

The efflorescence, said to occur about the head, neck, face, chest, and back, though searched for, was not apparent during the epidemic.

No case during any stage of the disease, or even after death, presented the noted and characteristic orange hue of the skin, as seen in some epidemics. The skin was dry, hot, and harsh, and often resisted, for a long time, the effect of counter-irritants, such as croton-oil and blisters.

When black vomit occurred, it was invariable after the subsidence of the fever and during the period of calm. That symptom, it was remarked, more commonly appeared upon the decline of the first stage.

By far the most remarkable symptom which presented itself during the epidemic was total blindness with dilatation of the pupils. It was present in only 70 cases; in one of those the disease proved fatal, while in the other recovery took place, and the eye-light was completely restored.

The pulse was not usually as frequent from the commencement of the attack as the state of the respiration and temperature might warrant.

Within one hour after the reaction from the chill, the thermometer frequently registered from 102 to 104.

The temperature was taken under the tongue or in the rectum. The same want of correlation between the range of temperature and pulse, which had been noted by Dr. White in previous epidemics of yellow fever was strikingly repeated during the one under consideration. The pulse and heat of skin, as noted by crude touch, commonly indicated an entire subsidence of the paroxysm within twenty-four or thirty-six hours; but the thermometer, like a cautionary signal of danger, showed that an elevation of temperature was present throughout the period of calm. The pulse, condition of the skin, and other symptoms, often indicated complete defervescence of the fever; but at the same time the thermometer rendered it apparent that the paroxysm was at its height. In the event of any dangerous complication, the thermometer rose suddenly and rapidly, and in two cases 107½ F. was reached, and yet the pulse remained at about 100.

The thermometer always afforded the first reliable information regarding approaching danger or convalescence. According to the thermometer, the duration of the first, or febrile, stage did not exceed four days, commonly about three; and the second stage rarely lasted more than twelve hours. Patients, under the treatment instituted, ordinarily glided so insensibly through the second stage into convalescence that it was only by aid of the thermometer the line of demarcation could be ascertained.

#### MIXED CHARACTER OF THE EPIDEMIC.

The mixed character of the epidemic was indicated by the following facts: By the remarkable mortality among the negroes; by the singular fatality attending cases which occurred among inured natives and their inhabitants who, from acquired acclimation, had ordinarily escaped the infection from yellow fever poison alone; by the unusual percentage of deaths which occurred among children under twelve years of age; by the modification which ensued in the virulent character of the pestilence after the occurrence of rains sufficient to wash out the drains; by the abatement in the malarial element of the disease after light frosts round the limits of the city.

#### TREATMENT.

The fever, inflammatory at the commencement, became typhoidal when under way; hence great care was exercised to exclude all remedies which had depressing tendencies.

The general plan of treatment was as follows—dejection being made to suit certain contingencies:

Absolute rest in the horizontal posture was enjoined; the patients not being permitted to rise from their pillow for any purpose.

Strict abstinence from food was enforced throughout the first stage; occasional mouthfuls of seltzer-water were allowed, and pellets of ice were allowed without stint.

When the patient was seen early after the seizure, a hot turpentine foot-bath was ordered, and ice applied to the head.

The medicinal treatment was invariably commenced by administering a single powder, made up as follows:

R Calomel,  
Sodæ sup. carb. . . . . ʒiij gr. x.  
Quina Sulph. . . . . gr. xx.  
M.

That combination never failed to bring about, within a reasonable length of time, one or two moderately consistent evacuations from the bowels, and bilious in character. There was no tendency to hyperpurgation as the result of the dose, but, on the contrary, enemata were sometimes required throughout the subsequent management of the case. The effect of the powder was to diminish the frequency of the pulse within from six to eight hours, without a correspondingly prompt abatement of the temperature. Frequent spongings of the entire body with tepid water were grateful.

The backache was always promptly relieved by the steady application, over the loins, of flannels steeped in whiskey and laudanum. As soon as the pain in the back was subdued, croton-oil was applied over the region of the kidney; such action was undertaken, under the belief that those organs suffered from the very commencement of the fever.

Four hours after the administration of the first powder, ten grains more of dry quinine were placed upon the tongue with a pellet of ice, and such dose was repeated every two hours during the continuance of the first stage. As long as the temperature continued to rise, or maintained a steady high rate, the quinine was persisted in; but as soon as any tendency to decline in temperature was noted, the quantity was diminished one-half, and camphor, for its diffusive stimulant and sudorific effect, was given in combination with it every four hours; and the two were continued until the thermometer indicated a normal temperature.

If the quantity of quinine was reduced too soon, the temperature and pulse were certain to rise; and it was always singularly difficult to bring them back to the point of departure. The quinine did not seem to disturb the stomach; but, on the contrary, when nausea supervened the persistent administration of it alone would quiet that viscus—a result which the doctor was inclined to attribute to the fact that the alkaloid was a basic compound, and therefore consumed the peculiar acid known to be so abundant in the stomach throughout this fever, and which prevented not only the direct source of irritation, but largely entered into the composition of black vomit. In no case was the purgative effects of quinine, spoken of by some, noted. In no stage of the disease did ammonia compounds agree. The system seemed to be surcharged with that alkali.

The treatment, when instituted early, invariably tended to shorten the duration of the first stage, and very materially modify the severity, if it did not prevent, the succeeding stages. In cases presenting hurried and oppressed breathing or sighing, the surface of the thorax was bathed with a liniment composed of croton-oil, chloroform, and turpentine, and repeated every three hours until some redness of the skin was produced.

Opium in all of its forms was regarded as dangerous, and never given until convalescence was fully established, and then only in great moderation.

After the first stage purgatives were not administered, and laxatives of the blandest character, in the form of enemata, only were employed.

The slightest tenderness upon pressure over the epigastrium, or eructations after the first thirty-six hours,

were regarded as definite indications for the use of blisters, which were at once applied over the entire abdomen. In case hemorrhage threatened to take place from the blistered surface, it was controlled by dressings of tissue-paper, with tannin or persulph. ferri ointment.

Stimulants were administered very early and throughout the progress of the case, and were essential during convalescence.

Every case which presented torpor of the capillary circulation, at the commencement of the second stage, was put upon the use of turpentine emulsion, with or without camphor, and the results were favorable.

When evidences of decline appeared, as indicated by the pulse and temperature, nourishment was cautiously administered in the form of thin chicken broth or beef-tea; it was given in teaspoonful doses at regular intervals. Milk invariably disagreed, even when combined with lime-water. All starchy compounds were forbidden, as they predisposed to flatulence. Especial attention was paid throughout to the function of the kidneys; ordinarily they caused but little anxiety. The urine was frequently diminished in quantity about the first day; and in two cases suppression caused alarm, by persisting over sixteen hours.

The doctor saw three deaths from collapse.

Black vomit was rarely seen, and those exhibiting it recovered with the rest, though more slowly. Convalescence was materially accelerated by the use of the muriate tincture of iron. DR. WHITE'S paper being open for discussion—

DR. J. C. PETERS inquired with regard to the probable character of the epidemic, providing importation of the yellow-fever germs had not taken place. Malarious yellow fever was not always distinguished from specific yellow fever; an important distinction, for the reason that one was probably not so infectious as the other.

DR. WHITE replied that probably the epidemic would not have been so virulent, nor affected so many. It might not have affected the negroes, but in the present epidemic they suffered severely, whereas they ordinarily escaped the malarious yellow fever. A malignant specific cause was engrafted upon the disease in the present instance, which, he claimed, was of exotic origin.

DR. PETERS made inquiry regarding the evidence of contagion; whether the disease was transmitted from one person to another through the exhalations from the body, or by means of articles of clothing, or through any of the excretions from the body, or whether it ran through families.

DR. WHITE replied that there was no evidence of contagion in the sense of communicating the disease from one person to another by direct contact; the cases in general rather showed to the contrary. The disease did not run through families, nor did it specially affect those who visited the sick, but rather struck down individuals who had been subjected to the three influences named.

In answer to inquiry, Dr. White stated that no post-mortem examinations were made. No deaths occurred when the treatment mentioned was thoroughly carried out.

After some remarks by Dr. A. N. Bell, the discussion was closed by Dr. Garrish, and the Academy adjourned.

CORRESPONDENTS sending us papers will please mark the items to which they desire to call our attention.

## Correspondence.

### ERYSIPELAS AND PUERPERAL FEVER.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Apropos to the discussions respecting the etiology of erratic erysipelas and puerperal fever, and the relations they bear to each other, I desire to record the following case.

Mrs. C., *æt.* about 37, a well-developed muscular woman, was delivered of a healthy child, in my presence, the afternoon of Feb. 16, 1876. I think this was her fifth confinement. At the time of her accouchement she was suffering from quite a hard cold.

There was nothing of special note in the case for the succeeding five or six days, except that she suffered considerably from a prolapsed condition of the rectum, which was the seat of small hemorrhoidal tumors.

Feb. 23d or 24th, she complained of soreness of extremity of the nose, to which I paid little attention, presuming it to be the result of her cold. Two or three days subsequently I was called again to see her. At this time there was marked swelling of the nose, accompanied with fever and severe headache. The case proved to be one of well-marked phlegmonous erysipelas, involving in its progress most of the face, one ear, and a portion of the scalp, lasting ten or twelve days.

There was no suppression of the lochia during the erysipelatous inflammation, at least not to exceed a portion of one day. I had attended no case of erysipelas for many months previous, neither do I know of other cases occurring under the care of other practitioners in this locality.

The interesting inquiry suggested by this case is, why did not this woman have puerperal fever?

Very respectfully yours,

WALTER B. CHASE, M.D.

WINDHAM, GREENE CO., NEW YORK, Dec. 11, 1876.

### ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from December 31, 1876, to January 6, 1877.*

BROWN, J. R., Surgeon. To report in person to the Comd'g General Mil. Div. of the Atlantic, for temporary duty in the Medical Director's Office of that Division. S. O. 266, A. G. O., Dec. 28, 1876.

BILL, J. H., Asst. Surgeon. To report in person to the Comd'g Officer, Dept. of the South, for assignment to duty. S. O. 266, C. S., A. G. O.

FRYER, B. E., Surgeon. To report in person to the Comd'g General Dept. of the Missouri, for assignment to duty. S. O. 266, C. S., A. G. O.

BENTLEY, E., Asst. Surgeon. Leave of absence extended one month. S. O. 1, A. G. O., January 3, 1876.

ADAIR, G. W., Asst. Surgeon. Leave of absence extended 15 days. S. O. 1, Mil. Div. of the Missouri, January 2, 1877.

CRAMPON, L. W., Asst. Surgeon. Assigned to duty with 2d Battalion, 13th Infantry, New Orleans, La. S. O. 258, Dept. of the Gulf, Dec. 30, 1876.

By direction of Secretary of War, the Army Medical Board, convened in New York City by S. O. 149, A. G. O., July 10, 1874, is dissolved. S. O. 266, A. G. O., Dec. 28, 1876.

MILLER, GEO. MCC., Asst. Surgeon. His resignation accepted by the President to take effect January 1, 1877. S. O. 266, A. G. O., Dec. 28, 1876.

## New Instruments.

### A NEW ATOMIZER FOR USE IN ANTI-SEPTIC SURGERY.

By H. T. HANKS, M.D.,

NEW YORK.

At my suggestion and direction, Stohlmann, Pfarre & Co., 117 East 28th street, have constructed the apparatus represented in the accompanying cut. The stand,

boiler, and lamp correspond in design to the common atomizer, now so generally used for inhalation purposes, but are much larger. The open glass vessel for holding the antiseptic fluid has a capacity of one pint, and is held in position over the boiler in a shallow metal cup. The latter is made to move forward and backward by means of a thumb-screw which is attached to an erect rod, fastened at the base of the apparatus. The rod in the cut is necessarily concealed from view. There is a small stop-cock arrangement low down at the side of the glass vessel, thus regulating the amount of antiseptic fluid which flows downward to the atomizing points. The long metal arm, into which is fastened in the usual manner the glass or metal spray-producer, is attached to the boiler by a kind of elbow-joint, thus enabling the spray to be projected forward at any angle. The alcohol lamp has a large tube for the wick, and over this is a second tube which slides up and down by means of a ratchet. The handle of the ratchet is seen in the cut. It readily controls the size of the blaze, the degree of heat, and the amount of steam produced. Great care should be exercised in selecting a suitable atomizing point. With a proper point a coarse or fine spray may be produced, according to the amount of antiseptic fluid admitted through the stop-cock. The force of the spray will depend upon the *blaze*, and the consequent amount of steam; and the angle of the arm will regulate its direction.

The apparatus thus constructed will supply a suit-

able spray for a two hours' operation, as the antiseptic fluid can be replenished as required. I claim for it its portability, small size, safety, durability, and cheapness. The cost is about \$15.00, and every way contrasts favorably with the Lister or Sass apparatus.

DECEMBER 18, 1876.

DEATH FROM CHLOROFORM.—On Friday, January 5th, a death following the administration of chloroform occurred in the office of a dentist of Rahway, N. J. Walter E. Lewis, a lad aged 14 years, shortly after having taken a hearty supper, stopped in company with a younger brother at the office of a dentist in that place for the purpose of having a tooth extracted. He was accordingly seated in the operating chair, and the administration of the anæsthetic commenced without delay. An ordinary folded napkin was placed over his nose and mouth, and he was instructed to take forced and deep inspirations. After several of these had been taken, and a slight struggling had been controlled, the tooth was extracted, immediately after which there was a gasp for breath, a deep sigh, and the head of the boy rolled to one side and he was dead. The dentist, in alarm, left the boy in a sitting posture and ran for help. The nearest available help was Dr. Daly, but he being absent, Mr. Marsh, a student of his, answered the summons, and repaired to the place with a galvanic battery. It was not until his arrival, a period estimated at a quarter of an hour, that the deceased was placed in a recumbent posture upon the floor and any efforts made at resuscitation. Dr. Selover arriving shortly afterwards, resorted at once to artificial respiration, plied the galvanic battery, and administered hypodermic injections of ammonia, but all to no purpose. At the time he saw the child the pulse had ceased to beat.

An autopsy was held Jan. 8th, at the instance of the County Physician, Dr. F. B. Gillette, of Plainfield, N. J., assisted by Drs. W. Updyke Selover, H. H. James, John J. Daly, of Rahway, and Dr. A. Pettit, of Elizabeth, N. J.

The body was spare but well nourished. Cadaveric rigidity marked. On removing the coverings of the chest the muscles were found to be of a darker hue than normal.

The pericardial sac contained a slight excess of straw-colored serum. The heart was normal in size, the right ventricle showing the usual amount of adipose tissue upon its surface. The vessels of the heart were ligatured previous to removal, and on being severed a quantity of dark fluid blood escaped. The right ventricle was flaccid and contained about half an ounce of the same character of blood noted

above. The left ventricle was quite firmly contracted, and was entirely empty. No thrombi were found. All the valves of the heart were sufficient and healthy, and the muscular substance, on microscopical examination, was found to be free from fatty degeneration. The liver was of normal size but congested throughout, and both lungs were in the same condition, slightly crepitant on pressure, and discharging from the cut surfaces of the smaller tubes a frothy mucus.

The stomach was filled with a full and but partially digested meal, a portion of which found its way into the œsophagus by post-mortem gravitation. The mucous membrane of the organ was apparently healthy and showed no evidences of post-mortem digestion. The larynx and trachea were entirely free, as was also the fauces, which fact destroyed the probability of choking during any possible effort at vomiting. Both passages were, however, markedly injected with venous blood; the same was the case with the small intestines and kidneys, which otherwise presented a healthy appearance. The bladder was half full of urine. The peritoneum, except a slight congestion, was also normal.

The brain was carefully examined. Its substance appeared normal. Its surface shared, in the general, venous congestion to a slight extent. No abnormal amount of fluid was found in the ventricles.

**DONATIONS TO MEDICAL INSTITUTIONS.**—The will of the late Col. W. R. Vermilye bequeaths two thousand dollars to the New York Eye and Ear Infirmary, and one thousand five hundred to the Northern Dispensary, of New York.

**THE ALBANY MEDICAL COLLEGE.**—The medical profession of Albany have been much exercised of late in regard to the management of the medical school of that city, and have divided themselves into two parties; one directly connected with the college, and one which represents the majority of the outsiders. The latter, representing the majority, are dissatisfied at the manner in which the professorships have been farmed out. When a few places are to be filled, and there are a number of aspirants for them, this is to be expected; but the manner in which the outsiders seek to revenge themselves is somewhat novel. The college, which is the property of the city, declares its inability to pay the rental, and maintains that an equivalent therefor is given by the number of students which it entitles from different parts of the country, who leave their money with boarding-house keepers, and tradesmen generally. The remainder of the profession think it is a shame that the city should be thus swindled of its just dues, and in order to meet the emergency, have organized a new faculty, who propose to pay the full rent if the Common Council will place the buildings at their disposal. At last accounts the matter, as far as we can learn, was *sub judice*. It would seem, as a matter of policy at least, that the present faculty will discharge their pecuniary obligations at once.

**OFFICERS OF THE NEW YORK ACADEMY OF MEDICINE.**—At the annual election, held Jan. 4, 1877, the following officers were elected: President, Dr. S. S. Purple; Vice-President, Dr. W. T. White; Recording Secretary, Dr. H. T. Hanks; Corresponding Secretary, Dr. J. G. Adams; Treasurer, Dr. H. P. Farnham.

**JOURNAL PRESCRIBING.**—Wishing to save any unnecessary trouble in the future, on the part of anonymous correspondents who ask for medical advice through our columns, we will simply state that we cannot, and will not give any such advice.

**METRIC DOSES.**—The following table, from the *Pharmacopœia Germanica*, exhibits the *maximum* doses, under ordinary circumstances, of the medicines indicated, and beyond which physicians in Germany are not allowed to prescribe unless they add the *caution-mark* (⚡), thereby indicating that the excessive dose is intentional:

	Pro dosi grammies.	Pro die grammies.
Acidum arseniosum.....	0.005	0.01
"    carbolicum.....	0.05	0.15

Zinci valerianas.....	0.06	0.30

Remembering that the above are MAXIMUM doses, we must direct attention to Strychninum and its nitrate, the doses of which, as given, appear to us to be *excessive*.

**THE CONDITION OF THE STREETS OF NEW YORK** is simply deplorable. The heavy body of snow which fell recently has partially melted, and has become converted into a deep and disgustingly filthy slush; the car travel is impeded by frequent blockades; while walking for exercise and comfort, except in the upper portions of the city, is out of the question.

## A DISCOVERY IN PHYSICAL DIAGNOSIS.

By EDGAR HOLDEN, M.D.,

NEWARK, N. J.

IN pursuance of investigation shortly to be published, with instruments designed for the earliest possible detection of disease of the lungs, a simple phenomenon has been noticed which cannot but prove of value in cases of uncertainty or obscure disease. I have been unable to find any record of a similar suggestion, and present it with cases, trusting that it may facilitate the early detection of phthisis, and thus increase the prospect of cure by medication.

A soft rubber tube,  $\frac{5}{8}$  of an inch in internal diameter and 2 feet long, with simple end-pieces of thin metal, and of a diameter of  $\frac{3}{4}$  inch, will, when blown into with a little force, produce a rushing noise at its extremity. The same sound is produced by forced inspiration. This is the instrument required. If the patient be made to respire through this, the ear of the physician being applied to the chest, and particularly at the supra-scapular space, this rushing sound is transmitted with clear resonant volume. Diseases, however slight, exaggerates the sound, alters the pitch, or changes it in proportion to the solidity of the conducting tissues. Obliging the patient to hold the extremity of the tube away from the listener prevents distracting his attention from the transmitted to the real sound, as does of course also the closing of the free ear with the hand. A singularly magnified character is given to the respiratory murmurs, and the stethoscope is unnecessary. In thin persons, so great is the exaggeration of the natural sounds that, as with the stethoscope, comparison of the two sides may at times be requisite to prevent misinterpretation; but in local consolidations and small cavities it has proven invaluable. A few cases only are presented, and the device, for want of a more appropriate name, termed a "resonator," submitted to the profession, in the hope that it will do even more than is claimed for it.

CASE I.—Geo. W.—, et. twenty-two, in good flesh and apparently robust health, presented himself November 17, 1876, with a partial aphonia of six months' duration; cough very slight, and symptoms entirely laryngeal. Upon laryngoscopic examination the larynx was found of a dusky red, the ventricular bands congested, and the true cords of a bright pink color. The capitula Santorini not enlarged, and no suspicion of other than a local difficulty present. Failure to improve under the treatment by sprays caused a careful thoracic examination to be made on the 25th, and the following notes were taken: "Left lung exhibits normal respiratory sounds; vesicular murmur unimpaired; percussion resonance normal. Right lung: clear vesicular breathing; expiratory murmur hardly audible and not prolonged; a shade of dullness at the supra-scapular space, and faint transmission of the cardiac sounds, but no râles, and only the slightest approach to a tubular character of the inspiratory current, behind the upper edge of the scapula; no wavy or jerky character detected.

Under ordinary circumstances a diagnosis of freedom from serious disease would be given, as it should be borne in mind that unusual attention was bestowed upon the examination for the purpose of using the

resonator. Upon respiring forcibly through this, the right supra-scapular region gave hoarse, roaring rhonchus, creaking, and râles; that of the left being in comparison a soft and gentle murmur. Serious organic change, localized, but vital in character, was believed to exist, and this has since been verified by the symptoms of well-marked consolidation, softening, and distinctly purulent expectoration; the laryngeal appearances being now, Dec. 30, those of developing phthisis. The capitula Santorini are tumefied and somewhat oedematous, with a thin, purulent fluid exuding between them.

CASE II.—Miss L. K., et. twenty-four, a clear-complexioned young lady, weighing one hundred and forty-eight pounds, and the most unlikely subject for phthisis, came on the 8th of December with apparently a simple cold of a week's duration, hoarseness that common under such circumstances, and the feverish, aching discomfort no more than usual. Having on two occasions (Nov., 1870, and Dec., 1874) exhibited evidences of disease of the right apex, but without softening, she had become alarmed, and feared so severe a cold as now experienced would redevelop the difficulty.

The brief note of examination is as follows: "Dullness on right side posteriorly from the apex to the lower border of the infra-spinatus muscle; few sounds of any kind, and no râles. With the resonator sounds of old pleuritic adhesions are evident at supra-scapular space, exaggeration of *expiratory* sound and alteration of pitch, with a suggestive approach to crepitation over the whole of the upper third of the right thorax posteriorly; left lung sound."

The subsequent examinations need not be alluded to in detail. In brief, the old apex difficulty has become gradually definable as the congestion has subsided in other parts of the lung, and to-day (Dec. 31st), the cough, pain, and laryngeal symptoms are unmistakably those of consolidation and disease at the seat of former trouble.

CASE III.—J. F. S., et. 16, a tall but pretty well developed young man, came first under treatment as an office patient in June, 1876, with the following record copied, like the others, verbatim because of its brevity: "Cough for three months, short and irritable; pulse quick and cordy, 96; expectoration, yellowish-white; mother died of consumption two months ago; father suffers from chronic catarrh. Diagnosis, incipient phthisis—consolidation at the right apex; dullness, prolonged expiration, and occasional pain."

This case progressed favorably and seemed to recover until a "severe cold" supervened Dec. 1st, and the morning irritative cough changed to one severe and painful.

Thoracic examination Dec. 23d, although carefully made, seemed to disprove the former diagnosis, and the resonator was used with the effect of developing clearly an abnormal intensity of the bronchial breathing at the right apex above and posteriorly, but not under the clavicle; the expiratory sounds were morbidly clear and prolonged, but without râles at any point over either lung. Evidences of subacute inflammation, however, of the larger bronchi were clear, and the treatment was adapted accordingly.

CASE IV.—This and the next case are added as of especial interest. Mr. J. L. C., et. 23; thin and pale, but in good vigor; a telegraph operator by occupation; came in on the 19th of December with a severe cough, said to be of one week's duration. A morning cough, however, has been experienced for several months; expectoration chiefly in the morning, and greenish.

The notes are as follows: "Right thorax anteriorly; clear transmission of heart-sounds beneath the clavicle; no râles. At supra scapular space, expiratory sound prolonged; inspiratory sound of a sibilant, bronchial character; dullness slight; no râles posteriorly. Respiratory sounds on the posterior aspect of the left lung exaggerated, but not more than is frequently observed with impairment of the right."

On comparison of the two apices with the resonator, the transmission at the supra-scapular space on the right side was found somewhat greater than on the left, but no râles and only slight creakings were developed. Upon listening over the middle lobe of the left lung behind, the hoarse roar transmitted was most marked. Up to this time no questions had been asked. To test the observations I said, with some hesitancy: "You have pain at this part of the left side?" "Yes," he replied, "great pain and soreness upon breathing."

"You have had, at some former time, trouble at the top of the left lung, and probably hæmoptysis?" "Exactly," he said, "but it was five years ago; there is no pain or trouble now." I repeat the exact words because they were so strongly impressed by the circumstances.

Here, then, in the left lung was the seat of the new trouble; the old being quiescent, and treatment for the acute, and not the chronic disease, was successfully instituted.

CASE 5.—This case is given because typical in some measure of a class of rapidly developed apex disease not hard to recognize, but illustrating the magnifying power of the simple device under consideration.

James J. J., aged fifteen, referred for diagnosis by the company by whom he is employed as clerk, presented himself Dec. 30, 1876, with the following brief history:

"Cough of six weeks' duration; pulse, 90; afternoon fever; night sweats; aphonia, greenish expectoration, etc."

Laryngeal examination shows trachoma due to tubercular granulation, on the right vocal cord, with tumefaction of the capitula Santorini.

Physical examination exhibited all the evidences of a small cavity in the right apex and consolidation at the apex of the left. With the resonator the hoarse roar like the surf seemed to bring the cavity almost against the ear, while the râles and creaking sounds were intensely magnified. On the left side the exaggeration of all normal and abnormal respiratory murmurs over a clearly definable area left no doubt of disease which must soon overwhelm.

As a brief summary of observation with this device it may be remarked, that it intensifies the sounds of vesicular dilatation, whether in a normal or morbid state. It intensifies the tubular sounds which, to the unassisted ear, are sometimes partially drowned by the neighboring healthy murmurs, and it exaggerates to painful hoarseness the evidences of air in cavities. Further experience will undoubtedly define more clearly the amount of assistance it will render in a disease which is manageable only in proportion to the promptness of its early detection.

## NEAR-SIGHTEDNESS IN THE PUBLIC SCHOOLS.

REMARKS MADE BEFORE THE MEDICO-LEGAL SOCIETY OF THE CITY OF NEW YORK, JAN. 3, 1877.

By CORNELIUS R. AGNEW, M.D.

MR. PRESIDENT AND GENTLEMEN—When asked to come before the Medico-Legal Society and make some remarks regarding the sanitary condition of our public schools, I was not aware of the course the discussion had taken, and did not charge myself with the duty of preparing a paper for the Society. It is true that for many years I have been interested in endeavoring to determine what the influence of school life is upon school children, and to separate those effects which may be justly attributed to life inside of the school houses, from those which might perhaps, with more propriety, be traced to certain conditions in the life of the children at home or elsewhere, outside of the school-houses. I think it is very important, in determining the effects of school life, that we should study the entire life of the child, as far as possible. We should take into account questions of heredity, and the hygienic conditions, to which the child is subjected at home, so that we may be able to know whether the child is likely to be a good tissue-builder. Because, as we all know, the effect produced by that part of the life of the child spent in the school-house will depend very much upon the heredity of the child, and upon the way in which each particular child builds its tissues. Many things, which might produce conditions grave in character in children of less stamina, may be borne with impunity by the robust. There is difficulty in separating the effects produced in school-houses from those produced by hereditary tendencies. I think this is a most important separation, and one which should always be borne in mind while making up our estimates upon the sanitary condition of the public schools. I was very much interested in the reports of Colm. of Breslau, published many years ago, containing observations as to the condition of the eyes of children in the villages surrounding that city, and in the school-houses of the city, and in its University. He found that, among the children in the villages, the amount of near-sightedness was very small—not exceeding two per cent. He made this result a basis for further operations, assuming that two per cent. might be accepted as indicating as near an approach to the normal eye as found anywhere, and continued his examinations through the primary and other schools of the city of Breslau, and into its University. He found through all the schools, as they rose in grade, a progressive near-sightedness among the pupils, until the University was reached, where it was found to be present in a most appalling ratio, reaching as high—if memory serves me—as sixty or seventy per cent. Now we all know that the peasant children in that country live in a state of comparative simplicity, and do not use their eyes to any great extent upon work which involves strain. Other observers, in other parts of Europe, followed with observations made in the same direction, and reached nearly the same results. When I came to consider the subject here, and talked to some of my friends concerning it, I was met with the statement that in this country the conditions were peculiarly favorable for the children; that in Germany the dietary was not as good as here; that the school-houses were not so well built; that there was a system of education in

CONTROL OF SYPHILIS.—Dr. J. R. Black, of Ohio, is another advocate for the examination of males previous to their entrance of houses of prostitution. He advises that the manager of the house perform this function, and that if any ulcer or abrasion is noticed the visitor must be denied admittance.

that country which was much more severe than that in practical operation here; and that the children were put in those schools, and kept under that system continuously, from the tender age of six or seven years until they had passed through the University; and that this continuous strain, added to the dangerous sanitary construction of the school-houses, and the deficient salubrity of the homes, produced a state of affairs which could scarcely be expected to be present in this country. As a matter of course, I was not able to accept such a statement, and it occurred to me to have tables arranged, like those of Cohn, and try and have observations made in the city of New York, and also in the cities of Brooklyn and Cincinnati. I selected New York as the great metropolis, supposing that the children of its population would perhaps show as quickly as those of any other city, the effect of straining the eye; and then taking the children in a city like Brooklyn, a city which is a little more provincial than New York; and lastly Cincinnati, where perhaps less strain was brought to bear upon the eyes of the children than in either New York or Brooklyn. I obtained the assistance of Drs. Prout and Matthewson, of Brooklyn, and asked them to obtain admission to the best schools of that city—schools in which the drill was most unrelenting. I also sent some of the tables to Dr. E. Williams, of Cincinnati. Drs. Ayres and Williams examined the eyes of a large number of children in the schools of that city, taking, without special selection, children from the primary, intermediate, and high schools. In that manner he examined the eyes of children who were quite young, and from that up to the age at which boys were sent into colleges. Some of the tables were also given to Dr. W. Cheatham, the house-physician of the Manhattan Eye Hospital, of New York, and he was given permission to make similar examinations in the New York College. That college stands at the head of the public school system. The boys reach it by merit, and they may be considered—so to speak—as the cream of the system.

When these tables were returned, and the observations summed up, it was found that the result obtained in New York, Brooklyn, and Cincinnati had a striking correspondence to those obtained in Breslau; and that near-sightedness increased as we ascend from the lowest to the highest schools in New York, Brooklyn, and Cincinnati, in about the same ratio as in the city of Breslau. We, of course, then immediately rejected the idea that the children of Breslau and its vicinity were under influences peculiar to that country. I then felt very desirous of arriving at some conclusion, if possible, as to how far the system of education generally pursued in our schools might be charged with bringing about, in the eyes of scholars, a state of affairs which intelligent persons would be compelled to regard as objectionable. Now, while I recognized that this general increase of near-sightedness was deplorable, I by no means was forced to the conclusion that the schools themselves were to blame in this country, in so great degree as previously supposed, and as many allege. I have no doubt but that work done in schools may come in as a large factor in the production of this condition of the eyes, but I am not prepared to give any opinion as to the exact value of the factor. Statistics are like a two-edged sword—they cut both ways—and it is the part of wisdom to be careful in making deductions from them. While, therefore, there was found to be an increasing amount of near-sightedness in these schools, I was not able to satisfy myself as to how

much was due to conditions existing in the schools, and how much due to heredity, habits of life; in other words, to conditions existing in the habits and homes of the scholars.

Progressive near-sightedness is a disease. A near-sighted eye is not a normal eye. When the child is born in the normal state, the eye is not near-sighted. Now, the eye is an organ which is plastic when the child is born; it is in a condition to be changed in its shape; its tissues are in a condition to be modified by the use which is made of the organ. Commonly the child goes on until it reaches the age of eight or ten years, perhaps a little older, when it is observed that it has to hold whatever it is looking at a little nearer to the eye than previously, and then, on examination, reveals the fact that the eye is near-sighted. If you follow such a child up to the age of twenty-five or thirty years, it will be found that the near-sightedness has doubled, and perhaps quadrupled. Now, we know, by means of the ophthalmoscope and other means, that the near-sighted eye is changed from the spherical to the elliptical, or oval form, and that progressive myopia is always marked by change in the shape of the eye. Inasmuch as the eye is made up of living tissue which is constantly undergoing the process of waste and repair, you can readily perceive that the law inducing the amount of such waste and repair is very much determined by the character of the tissue-building process in each child, and the way in which that child uses the eyes. For example, the child is allowed to sit, perhaps for hours, with the body partly bent, and the face inclined towards a book which rests in the lap while reading; here the accommodation of the eyes is taxed in looking at a minute object while they are in a bad condition, and all this time waste and repair is going on as best as it may. The child would go blind in an instant were there no tissue reproduction. Now, if the eye is used while the body is in an unfavorable position, it cannot be nourished as it should be, and the pressure of the muscles upon the eyeball and the action of the crystalline lens in focalization must bring about changes which lead to this progressive form of disease. Then let the child go at an early age into a school house where perhaps it will be placed upon work with books, slates or copy-books which could be better done by means of the black-board or models, and again the eyes are strained, and so the unfavorable effects are continued.

In accordance with the plan which has been detailed, the eyes of 1479 students were examined. Of these, 630 were in Cincinnati, 549 in New York, and 300 in Brooklyn.

In Cincinnati, the students examined were of the primary and intermediate schools, and classes of the normal high schools; in New York, of the introductory, freshman, sophomores, junior and senior classes in the New York College; in Brooklyn, of the Polytechnic Institute. In nearly all cases the refraction was determined by trial glasses, and afterwards corrected by the ophthalmoscope.

TABLE I.

The first table, embracing the examinations of the 630 children in Cincinnati, gives, for the district schools, 209 scholars, and of these there were 83½ per cent. who had natural, or what is called emmetropic eyes. In those schools the near-sightedness rate was 10 per cent. In the intermediate schools, the eyes of 210 scholars were examined, and of these 80 per cent. were natural, and 14 per cent. near-sighted.

In the normal high-schools, the eyes of 210 stu-

dents were examined, and of these 78 per cent. were emmetropic, and 16 per cent. near-sighted.

TABLE II.

In the second table we have the results of examinations made of the eyes of 549 students in the New York College.

In the introductory classes, 57½ per cent. were found emmetropic, and 29 per cent. near-sighted.

In the freshman class 42½ per cent. had natural eyes, and 40 per cent. were near-sighted.

In the sophomore class no very material difference from what was observed in the preceding classes; but in the junior class 37 per cent. had natural eyes, and 56 per cent. were near-sighted.

In the senior class 50 per cent. had normal eyes, and 37 per cent. were near-sighted.

TABLE III.

In the third table we have the result of observations made upon the eyes of 300 students in Brooklyn. Of those, there were found in the academic department of the Polytechnic Institute 56 per cent. with natural eyes, and 10 per cent. near-sighted.

In the collegiate department, 158 students, 53 per cent. had natural eyes, and 28½ per cent. were near-sighted.

Summarized, it is found by these tables, that of the students examined at Cincinnati there were 10 per cent. near-sighted in the district schools, 11 per cent. in the intermediate schools, and 16 per cent. in normal high schools.

Of the students examined in the New York College, 29 per cent. of the introductory class were found to be near-sighted; 40 per cent. of the freshman class; 35 per cent. of the sophomores; 53 per cent. of the junior class, and 37 per cent. of the senior class.

Of the students examined at the Polytechnic Institute, Brooklyn, near-sightedness was found in 10 per cent. of the eyes in the academic department, and in 28 per cent. in collegiate department.

Now, if we find in a first-class organ like the eye, examined in early life and all through childhood, and also during middle life, that the effect of the use of that organ is to produce or aggravate a diseased condition, may we not, from what we see in this transparent organ, justly infer that during the same period of life damage is being done to other organs of the body which are not transparent, and in which morbid conditions cannot be so easily determined. This thought has made me feel a very great interest in these investigations. I believe that before we conclude these examinations certain results will be formulated by which parents at home will be able to apply the principles of hygiene much better than now, to the care of their children, the school-boy be placed under better instruction in the schools, and the school teachers much better qualified than now for the management of the scholars placed under their care.

It seems to me that the very etymology of the word education enforces the idea that the child is to grow better and stronger up through his school life, and that by proper regulation of his diet and management at home, by properly lighted school-rooms and properly constructed desks, and a better regulation of his hours of study, he should represent a much higher type of life when he has reached the age of twenty-five than when he is just taken in hand with the view of giving him book knowledge. We certainly should not damage the eye in the process of education, and I believe that the damage done to the eyes is to be taken as an index of that which is done to other organs of the

body. In closing, I must acknowledge my obligations to Dr. D. Webster for his invaluable assistance in the work.

## Progress of Medical Science.

**LITHOCLYSMY; A NEW OPERATION FOR VESICAL CALCULUS.**—Dr. Pignoni has designed an instrument by means of which he proposes to disintegrate and dissolve calculi while still in the bladder. He has found by experiment that nitric acid diluted with half its weight of water will rapidly disintegrate all forms of calculi, even those which contain cholesterine, the best solvent for which, however, is alcohol. Neither of these reagents exert any destructive influence on caoutchouc. In order, then, to destroy a stone while still in the bladder, it is only necessary to introduce a long caoutchouc bag into the bladder, to isolate the stone within this bag, to bring its open end out of the meatus urinarius, and to cause a double current of diluted nitric acid or of pure alcohol, if the calculus be composed exclusively of cholesterine, to pass through the bag. All this may be safely done with Dr. Pignoni's apparatus. It consists first of all of a straight tube, 7½ inches long, and open at both ends, through which a gum-elastic bougie passes. This is introduced into the bladder, and then the bougie is withdrawn leaving the tube *in situ*. The bladder is then filled with warm water, and the isolating sound introduced. This sound consists of a long metallic stem, to one end of which a flexible, elastic steel hoop is attached. The open end of a caoutchouc bag is fastened to the hoop, which is then compressed with the fingers and pushed into and through the canula. Upon entering the bladder the hoop resumes its original form, and by careful manipulation the stone, provided it be not incapsulated, may be seized and imprisoned in the sac. The whole of the caoutchouc bag is then pushed into the bladder and the isolating sound withdrawn, bringing with it the open end of the bag, and leaving the closed end in the bladder enveloping the stone. The interior of the bag is greased, and three or four tapes are glued to it longitudinally to keep it from embracing the stone too tightly. The reagent is introduced through a gold or platinum double current catheter. If the stone be of moderate size it can be dissolved in a single seance; but if it be too large for that, the solvent should be evacuated, and the bag washed out with common water, and then split open.

An extensive experience with the operation has convinced Dr. Pignoni that the increased temperature caused by the action of the solvent upon the stone, does no harm. Spontaneous rupture of the bag is impossible. Even if it should occur, however, little harm could result, for the bag being almost completely filled by the stone, the amount of chemical solvent contained in it would be small in comparison with the pint or more of water it would meet in the bladder.

The action of a voltaic current of electricity, a powerful agent for decomposing calculi, might also be employed in addition to the chemical solvents. When stricture of the urethra or an enlarged prostate interferes with the operation per urethrum, lithoclysm may be performed through the perineum or the rectum, or through the hypogastrium, in preference to lithotomy or lithotripsy.—*Le Mouvement Medical*, November 18th.

**CHANGES OF THE CILIARY PROCESSES DURING ACCOMMODATION.**—Prof. J. Hjort, of Christiania, narrates the case of a workman who was severely injured by an explosion of dynamite. In addition to his other injuries, there was also a complete absence of the iris of the right eye. The only other lesion to be perceived in the eye was a vertical wound of the cornea about 3 mm. in length. The lens remained in its normal position, the zonula of Zinn was intact, and the vitreous transparent. Vision soon became perfect. The ciliary processes could be seen very distinctly with oblique light, with the ophthalmoscope, and still better with Brücke's lamp under oblique illumination. The latter rendered it easy to study the relations of the ciliary processes during accommodation, and also their changes after the instillation of calabar extract. The results of these observations are, that by the act of accommodation or the contraction, provoked by the calabar:

1st. The dark margin of the lens became broader.

2d. The ciliary processes approached the axis of the eye and became swollen.

3d. The distance between the margin of the lens and the ends of the ciliary processes (the zonular space of our author) did not appear to suffer any change.

4th. The changes observed did not occur instantly, but required a very appreciable time, though not very long. The relaxation of the accommodation also occurred gradually.

The distance between the margin of the lens and the sclerotic was increased during the accommodation, and just sufficiently to correspond to the advancement of the ciliary processes.

Under the action of atropine, it may be that the ciliary processes moved backwards a very little, but it was impossible to notice any change of the zonular space.

Prof. Hjort has also examined several albinos, and he has found that the phenomena presented were precisely the same, except that in them the observations were made with greater difficulty.

These observations fully confirm the theory of accommodation formulated by Helmholtz, Graefe, and most modern physiologists. Becker, who has examined the eyes of several albinos, differs in this that he has found that the ciliary processes are drawn backwards during accommodation.

Prof. Hjort had observed the same phenomenon, but he explained this, at first, by the insufficient strength of the calabar used, later and principally by the fact that the retrograde movements of the ciliary processes are only illusory, and the latter become concealed further behind the scleral margin when the eye makes a slight outward movement during the examination. This happened once to our author, and probably also led to Becker's error. This explanation is also confirmed by the observation that the distance between the margin of the lens and that of the sclerotic is also diminished at the same time.\*—*Nordiskt Medicinskt Arkiv.*, 8de Bandet, No. 17.

**PARACENTESIS OF THE PERICARDIUM, WITH AN ANALYSIS OF FORTY-ONE CASES.**—Dr. John B. Roberts, of Philadelphia, gives an interesting résumé of this operation from the earliest times, with the indications for treatment and the general results that may be expected. Riolan first proposed it in 1649, but Romero performed the first successful operation at some time before 1819. Paracentesis is indicated when the effu-

sion is large and threatens to destroy life, ordinary treatment failing to produce absorption. The period that the surgeon must allow to elapse before tapping is as yet undecided. As a method of giving relief in chronic cases it is probably no more open to objections than is excision of the breast or tongue for cancer. The particular method of operating is now tolerably uniform. A small aspirating needle is to be used, so small that it simply makes a fine puncture that would not harm the lung, if that were pierced. The point recommended by Dieulafoy is in the fifth interspace, about three-quarters of an inch from the edge of the sternum. In fifteen out of thirty-four cases this point was chosen.

The dangers to be dreaded are wounding of the internal mammary artery, and striking the heart as it is thrown forward in systole. By adopting Dieulafoy's plan, the artery is avoided, as it lies from a quarter to half an inch from the edge of the sternum. Injury to the heart may be avoided by having a canula slide over or within the needle, thus guarding its sharp point. The heart may, probably, however, bear a certain degree of injury with immunity, according to Eve, Steiner, and others. Baizeau and Roger tapped the ventricle without doing harm, both patients surviving the operation, though in one case 150 and in the other 250 grammes of blood were drawn. As for the danger of the operation in these forty-one cases, regarding one in which the final result was not given, as a fatal case, the mortality was 53.66 per cent. But then the effusion in many of them was merely a single factor of disease; in fact, in seventeen there were other concomitant and often incurable affections. In five fatal cases no other disease was mentioned, which puts the mortality at 12.19 per cent., supposing it to have been from cardiac dropsy alone. Since the year 1850, of the uncomplicated fatal cases, the mortality has been 21.43 per cent., which though not so low as the figures given for all the uncomplicated cases taken together, is perhaps as low as in many other operative procedures that are regarded as perfectly justifiable. In acute rheumatic pericardial effusions the results have been excellent; where, however, the disease becomes chronic a perfect cure is almost hopeless, for, owing to the long continuance of the inflammation, the maceration of the heart and the pressure of the distended sac, the tissues have assumed new pathological characters.—*New York Med. Journal*, Dec., 1876.

**NEUROMA OF THE MEDIAN NERVE—RESECTION AND SUTURE OF THE NERVE.**—The notes of this case were read before the *Société de Chirurgie*, on November 8th, by M. Notta, of Lisiens. The patient, a man forty-five years of age, consulted M. Notta in September, 1875, for a small tumor in the anterior part of the forearm. This tumor was as large as a hazel-nut, movable under the skin, and not tender on pressure, but in consequence of a blow became the seat of very severe pains. It presented all the subjective and objective characters of a neuroma of the median nerve. The tumor was cut down upon and removed, and the two ends of the nerve which, in consequence of the retraction, were separated to the extent of an inch, were drawn together and held in contact by means of a metallic suture. The superficial wound was then united. Some days after the operation an attack of erysipelas supervened, but it was soon cured and the wound then cicatrized. After the operation there was anæsthesia of the parts of the hand supplied by the median nerve. Fornication soon set in. On the thirteenth day, sensation returned in the ring-finger, and on the sixteenth day it returned in the

\* Muscarine was also tried. The effect was the same as that of calabar, though much weaker.

thenar eminence. The palmar surfaces of the thumb, index and middle fingers regained their power of sensation more slowly and gradually; but eight months

after the operation, the patient felt as well with that hand as with the other. At the same time some trophic disturbances, which had taken the form of ulcerations of the index and median fingers, were cured. Microscopical examination showed that the tumor was an interstitial fibro-sarcoma of the median nerve, the nervous fibres being separated and spread out over the surface of the tumor.

M. Verneuil discussed this communication at some length. He thought the suture of the nerve useless. Careful study shows that the return of the nervous innervation after resection of a nerve, takes place from the periphery towards the centre. Thus, after resection of the lower jaw, the corresponding half of the lower lip is paralyzed; on the evening of the operation the prick of a pin is hardly felt in the median line; on the next day it is felt two or three millimetres outside of the median line, and so on. In M. Notta's case, the time intervening between the operation and the return of sensation to the ring-finger and the thenar eminence was so short that it is unreasonable to suppose that regeneration of the nerve and passage of the nervous influence along the newly-formed nerve-fibres could have taken place. The return of sensation was due to the establishment of collateral innervation through the agency of the ulnar and radial nerves. To support this view he cited a case of a young girl afflicted with permanent and extreme flexion of the fingers of one hand caused by a cicatrix in the front of the wrist. Sensation in the hand was preserved, and on that account M. Verneuil thought that the median nerve, and necessarily also the tendons of the deep flexor, were unaffected by the cicatricial band, which involved only the tendons of the superficial flexor. He operated with the view of isolating these tendons, but in doing so he cut a whitish cord, about 1 or 2 millimetres in thickness. About a centimeter of this cord was cut out, and on examination found to be a portion of the median nerve, which was, however, very much altered. After the operation he was surprised to find that the sensation in the hand was not affected in the least. In this case, consequently, the median nerve had no office to perform. The nervous influence previous to the operation did not pass through its fibres, and the hand was supplied by collateral innervation.

M. Tenier agreed with M. Verneuil, and thought, moreover, that suture of the nerve was dangerous, and that it was possibly the cause of the erysipelas in M. Notta's case.—*La France Medicale*, November 11th, 1876.

**VENOUS PULSE AS AN HABITUAL SYMPTOM OF THE PHYSIOLOGICAL ACTION OF CHLOROFORM.**—Prof. Léon Noël, of the University of Louvain, publishes a paper with the above title in the *Bulletin de l'Académie de Médecine de Belgique*. This remarkable phenomenon does not appear to have been observed by any other writer. It appears always at the same period of the anesthesia, that is, during the period of awaking. The internal jugular veins, the subclavian veins, in more than half the cases the external jugulars, and sometimes even the facial veins, are then the seat of pulsations which are isochronous with the radial pulse. These pulsations appear very marked to the eye, but give only a very slight sensation to the palpating finger. A double undulatory movement takes place with each pulsation. Compression of the ex-

ternal jugular, in which vein the phenomenon is most easily studied, at the base of the neck, causes the pulsations in that vein to cease; on the other hand, they persist during compression of the vein in the upper part of the cervical region. They last about half an hour, diminishing gradually in intensity. During all this time the heart's action and the respiration present no particular modification.

Prof. Noël thinks that a venous pulse so marked as this indicates a profound perturbation of the functions of the heart. Its existence proves that the organism is still under the influence of the anæsthetic. In fact, numerous recorded cases show that death may occur from the influence of chloroform even when the inhalations have been suspended for some time. What is the mechanism of this venous pulse? Dr. Noël thinks that it is due, possibly, to an incomplete closure of the right auriculo-ventricular valve, consequent to the paralyzing action of the chloroform on the heart; on the other hand, it is not unlikely that the poison causes an engorgement of the vena cava and the right ventricle, which interferes with the escape of the contents of the auricle into the latter. Whatever its cause, however, the venous pulse indicates a profound functional disturbance of the heart; hence, it is important for surgeons to watch their patients attentively while they are reviving from an anæsthetic.—*La France Médicale*, November 18th.

**ABSCESS OF THE ABDOMEN SIMULATING A PNEUMOTHORAX**—Dr. F. Levison, of Copenhagen, reports the case of a woman twenty-two years of age, who entered the hospital with all the symptoms of a peritonitis caused by an ulcer of the stomach. Several days later, the percussion of the left subscapular region gave a tympanitic sound over an extent of three to four centimetres, while a dull sound was found above as well as beneath this tympanitic zone. Two days later the tympanitic sound had extended over the entire left surface of the back, as far as the spine of the scapula, and in these regions the respiration and the sound of the voice had an amphoric character. The diagnosis was made of a pyo-pneumothorax, caused by perforation of the diaphragm, and, to relieve the patient, two punctures were made in the seventh and eighth intercostal spaces. Considerable gas, but no liquid escaped; the stethoscopic signs remained nearly the same. A diphtheritic affection of the respiratory passages supervened and caused the death of the patient.

The autopsy demonstrated fresh adhesions between the stomach, the right lobe of the liver, the gall-bladder, the spleen, and the diaphragm. A cavity was formed by these adhesions, communicating with the stomach by a pretty large perforation, and containing gas and a little pus, but without any communication with the cavity of the left pleura, where, consequently, neither gas nor liquid were found. The diaphragm had been driven upwards in such a manner that the trocar necessarily passed through it to enter the cavity formed by the adhesions.

This case is quite remarkable from its rarity; it is rendered still more so by the support it affords to the theory which attributes the formation of the physical signs noticed in pneumothorax, and called amphoric voice and respiration, metallic tinkling, etc., to the modification of the pulmonary sounds by a stratum of air adjacent to the lungs, but without communication with the bronchi.—*Nordiskt Medicinskt Arkiv*, 8de Bandet, No. 20.

# THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, January 20, 1877.

## INTELLIGENT AND EFFECTIVE QUARANTINE.

THE report of the Health Officer for the past year develops some points in the experience of quarantine which are of interest to every one. Notwithstanding the fact that from May 15th to Oct. 15th, three hundred and sixty-three vessels arrived at New York from ports where yellow fever prevailed in a more or less epidemic form, not a single authenticated case reached the city. If we associate with this state of affairs the statement that during all this season rendered so unusual by the number of places in which yellow fever prevailed as an epidemic, not a vessel was so restrained as to retard her regular sailing, we are perfectly safe in upholding the system of quarantine which has led to such gratifying results. It would seem that, so far as facts and figures will allow us to draw any conclusions, the problem has at last been solved of effectually guarding against the possibility of infectious diseases entering our city, while at the same time the best interests of commercial circles have been amply considered and satisfactorily protected. It is but just to state that the principles upon which this consummation of the wishes of the people and the merchants are founded were established five years ago, by the present Health Officer; and to his laudable and untiring efforts in reconciling what have heretofore been conflicting interests, we owe what must now be considered a perfect system. Not only have numerous cases of yellow fever found their way to this port, but from February until the latter part of October (except during the month of May), there were thirty-nine patients with the disease actually treated in the hospital at Dix Island. Of this number eleven only died, showing a favorable percentage of recovery; which result, by the way, Dr. Vanderpoel attributes in a great degree to the airy and healthy location of the hospital. In regard to the means taken to prevent the spread of the disease the Health Officer remarks:

The presence of yellow fever at Brunswick, Savannah, and Charleston, all lying within a point from which steamers could complete this passage within the average time assigned as the incubation period of the disease, rendered it necessary that some arrangement should be made whereby the commerce from those ports should remain unrestricted. It was directed that no passengers be taken on vessels coming from those ports. This left me to deal with the crew and cargo only. Full hygienic precautions were suggested to the steamers plying between Savannah and New York, which, on their part, were faithfully carried out. The usual course was pursued with reference to the vessel and cargo as with all vessels coming from infected ports. The vessels made their trips during the whole epidemic with their accustomed regularity; indeed, for reasons about to be stated, extra vessels were placed upon the route. So far from New York being a loser, she was a gainer, in a commercial aspect, from the fever epidemic at Savannah. She was the only port on the Atlantic coast which permitted free commercial intercourse with the infected city. With Baltimore, intercourse by sea was almost wholly interdicted, while at Philadelphia an entire embargo was laid upon all communication by way of the sea. The agent of the Philadelphia and Savannah Line complained "that not only was all intercourse interdicted, but the authorities would neither allow his steamer, then at Philadelphia Quarantine, to discharge, nor depart for another port." It seems scarcely credible, after the full light of recent experience, so suicidal a policy should have been pursued. Had the fever fomites really existed upon the vessel, no decision could have been adopted which would so likely cause the epidemic to appear. Experience has fully shown that but the nidus of fomites allowed to remain unmolested in the hold of a vessel will so rapidly develop as soon to make the vessel a pest ship, whereas if the cargo is speedily removed and the vessel thoroughly cleansed, danger is reduced to its minimum factor.

The consequence of this embargo was, that not only was an excess of cotton sent from Savannah to this port, as compared with previous years during the same period, but all the vessels trading from Charleston, Wilmington, and even Norfolk, were tasked to their utmost carrying capacity. Sanitary measures and commerce need not, therefore, be antagonistic, and in this instance the former aided the latter.

### UNIFORMITY IN METEOROLOGICAL OBSERVATIONS THROUGHOUT THE WORLD.

THE tendency of scientific men to establish uniform systems of observation throughout the world has a fresh exemplification in the recent action of the Signal Service Bureau regarding simultaneous meteorological records. At the meeting of the Meteorological Congress of Vienna in 1873, it was proposed that at least one uniform observation should be made at a specified time at every signal station in the world, and that the results should be embodied in suitable synopsis charts for universal use. In conformity with this suggestion the Signal Service Bureau has, as the result of an extensive correspondence, established the requisite co-operation between the United States and Algeria, Austria, Belgium, Great Britain, Denmark, France, Germany, the Netherlands, Norway, Portugal, Russia,

Spain, Sweden, Switzerland, Turkey, Greece, Canada, the Hawaiian Islands, Dutch Guiana, and Japan.

The Secretary of the Navy issued an order Dec. 25, requiring that, on every naval vessel, and at every naval station, wherever they may be, on every sea, in storm or sunshine, one observation shall be taken and recorded daily at precisely 7.35 A.M., Washington mean time. These observations must embrace, when practicable, atmospheric pressure, temperature, wind, rain, reading of wet-bulb thermometer, sea-swell, and weather. The record of these observations is to form a part of the record of the United States bulletin of international meteorological observations, and the greatest care and promptitude are enjoined in making it. A copy of the bulletin will be sent to every capital.

The Army and Navy have agreed to co-operate in this great work, and all that is needed is the organized assistance of the mercantile marine, to place not only the entire northern hemisphere under a system of daily meteorological observations, but at stated intervals the entire civilized world. It is impossible to calculate the benefits of these reports to scientific men generally, and especially to those engaged in the study of meteorological influences upon disease.

#### NEAR-SIGHTEDNESS IN SCHOOL CHILDREN.

THE remarks of Dr. Agnew on the near-sightedness of school children will doubtless command the attention which they deserve. The conclusions arrived at may possibly disappoint many who have given the matter only a superficial study. While, however, we may congratulate ourselves that the case is not so bad as might have been anticipated, we must not be tempted to draw conclusions too hastily. In the face of the fact that near-sightedness increases in a given ratio with the character and amount of study, it is impossible to escape the conviction that there is a very significant relation between cause and effect. Viewing the question in the light of the necessity of reforms in our schools, it does not matter, however, whether we take the eye as a single organ or as a part of the general economy,—whether, in fact, it can be injured directly by absence of proper light, by abnormal focal adjustment and the like, or indirectly damaged by the violation of general hygienic conditions. In any event, every supposable cause of the trouble should, as far as possible, be removed. Indeed, if we assume with the distinguished observer that the pathological processes which take place in the eyes of school children are associated with similar changes in other organs, and all of these are due to faulty school management, we have fresh incentives for more extended observations, and are likely to discover more arguments in favor of radical changes in the manner of educating our children.

#### SUBURBAN NUISANCES.

STATE SENATOR WAGSTAFF has taken to heart the interests of the dwellers upon the East side of New York, who have suffered for years past from the sickening and noxious odors wafted from the Hunter's Point oil factories. At the commencement of the session he introduced a bill which gives the Board of Health of any city in the State a right to apply to the courts of the county in which the nuisance-creating factory is situated, for an injunction upon its owners to abate the nuisance. The Board of Health may also, in case the owners of the factories neglect to comply with a request that they put an end to the nuisance, bring a suit against them and recover \$250 for every refusal or neglect.

The passage of this bill will confer an incalculable benefit upon thousands of individuals who have heretofore despaired of any relief.

#### INSPECTION OF IMPROPER FOOD.

WE are surprised to learn from an address delivered by the President of the Health Board, at a recent meeting of the Public Health Association, that in consequence of the want of any appropriation there were no officers engaged for the inspection of meats. The omission of this provision is a very serious one, and it is to be hoped that during the present session of the State Legislature some means will be adopted to secure the desired end. In all the countries of Europe special commissions are formed at great expense for this purpose, and the public at large is as much if not more interested in this work than in any department of public health. In any large city, the fact of the non-existence of gentlemen qualified for the duties of these offices is such a reflection upon the sagacity of our law-makers, that we are in hopes that the necessary steps will be taken without delay to secure the required funds and appoint the proper persons to the offices.

#### ANOTHER DEATH FROM CHLOROFORM.

CLOSE upon the report of the chloroform accident at Rahway, N. J., comes an account of another death by the same agent, occurring in London. In the latter instance, every precaution was taken to guard against accident, but to no purpose. A full report of the case will be found in another column. On reading over the account of the post-mortem, we cannot help regretting that a microscopical examination did not settle the question concerning a supposed fatty heart.

AN EFFICIENT DISINFECTANT.—The *Lancet* says: "No better agent could be used than the bisulphide of carbon, which on ignition involves sulphurous acid in vapor. The substance is not costly, and may be burnt either in an ordinary spirit lamp or in an open dish. It should be used with caution, as it is extremely inflammable."

## Reviews and Notices of Books.

TRANSACTIONS OF THE NEW YORK ACADEMY OF MEDICINE. Second Series. Vol. I. New York: D. Appleton & Co. 1876. Svo, pp. 458.

THE present volume of Transactions contains the papers which have been read before the Academy during the past two years. As all of these have been published in abstract in the MEDICAL RECORD, it is unnecessary to do more than give our readers their title in order to enable them to judge of the character and contents of the work. I. Abscesses in the Right Iliac Fossa. Dr. Gurdon Buck. II. Abscesses in Right Iliac Fossa treated by Incision. Dr. E. Krackowizer. III. Absorption Bands in the Spectrum of Colored Organic Fluids. Dr. John C. Dalton. IV. On Anchyloses. Dr. Lewis A. Sayre. V. Spinal Paralysis of Adults. Dr. E. C. Seguin. VI. Mammary Diseases during Lactation. Dr. S. Caro. VII. Morbid Changes of the Medulla. Dr. Allan McLane Hamilton. VIII. Reparation of Brain-tissue after Injury. Dr. John P. Gray. IX. Disturbed Action of Heart and Functional Murmurs. Dr. J. R. Leaning. X. Prevention and early Arrest of Pulmonary Phthisis. Dr. E. D. Hudson. XI. Multiple Abscess of the Liver. Dr. S. W. Dana. XII. and XIII. Treatment of De-formed Pelvis. Dr. Isaac E. Taylor. XIV. Rheumatic Diathesis in Dermatology. Dr. H. G. Piffard. XV. Hospitals. Dr. W. G. Wylie. XVI. Diphtheria. Dr. C. E. Bellington. XVII. Rotation in Lateral Curvature of Spine. Dr. A. B. Judson. XVIII. The Spectroscope. Dr. G. B. Fowler. XIX. Epidemics of a Century. Dr. G. M. Smith. XX. Degeneration of Placenta. Dr. C. A. Leale. XXI. Incision and Dissection of Cervix Uteri. Dr. E. R. Peaslee. XXII. Chorea and its Treatment. Dr. Geo. T. Stevens, of Albany, N. Y.

The variety of the subjects named, and the thorough and exhaustive manner of their presentation, give a variety and value to this volume which cannot be overestimated. The typographical execution is excellent, and the general make-up of the work is everything to be desired.

THE MEDICAL MEN OF THE REVOLUTION: An Address before the Alumni Association of Jefferson Medical College, March 11, 1876. By J. M. TONER, M.D., of Washington, D. C. Philadelphia: Collins, Printer, 705 Jayne Street. 1876.

THE address by Dr. Toner gives evidence of extensive research, and forms a most valuable contribution to the historical literature of the medical profession. Surely in those days which so "tried men's souls," the physicians played a most important part, and their memories should not be covered with the dust of years. Dr. Toner has garnished their epitaphs, and their names again shine in a brilliant setting of labors in defence of human liberty.

A SKETCH OF THE LIFE AND WRITINGS OF LOUYSE BOURGEOIS. The Annual Address of Retiring President before the Philadelphia County Medical Society. By WILLIAM GOODELL, A.M., M.D. Philadelphia: 1876.

DR. GOODELL has stepped out of the beaten track, and given us an address which consists in an exceedingly pleasant review of the life and writings of the midwife to Maria de' Medici, the Queen of Henry IV. of France. The work upon which the review was based was printed in Paris in 1617.

## Reports of Societies.

## NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, Dec. 12, 1876.

DR. C. K. BRIDDON, PRESIDENT, IN THE CHAIR.

(Continued from page 27.)

## CARIES OF THE CARPAL BONES—RIGHT WRIST.

DR. MASON related the following case:

Sarah McG., aged between ten and eleven; highly nervous temperament; was seen first by Dr. Thomson, Jan. 31, 1870. She then complained of pain in the wrist, the dorsum of which was slightly swollen and a little red. Lead and opium was ordered; nothing further was seen of the patient for four or five days, when the wrist was found greatly swollen, patient suffering intense pain and very much run down. Feb. 5, 1870, I saw her in consultation with Dr. T.; at this time both the dorsal and palmar surfaces were greatly swollen and erysipelatous. Under ether, free incisions were made, both in dorsal and palmar portions of the hand, which gave escape to a large quantity of pus. Other incisions were made from time to time, and setons drawn through them; this relieved the condition of affairs very much. Three weeks after the first incision was made, a splinter of wood, one inch in length, came out of one of the openings. She then told us that during the preceding summer, while playing on a fence, she thought she ran a splinter in her hand; but not finding any trace of it at the time, thought no more about it. Soon after the escape of this splinter, one of the carpal bones came away. Extension was made and hand kept on a splint, which relieved her pain considerably. May 1.—The general condition having greatly improved, I advised an operation, dead bone being readily detected. May 5.—I removed the carpal bones of the second row, and the carpal end of the metacarpal bone of the middle finger, which was carious. The incision was on the dorsal aspect; no tendons were divided. I was assisted in the operation by Drs. Thomson and Carmalt. Patient made a rapid recovery. When I saw her last, at end of the following June, she could sew without difficulty and play on the piano.

## CARCINOMA OF THE COLON.

DR. LEWIS A. STIMSON presented a tumor of the transverse colon, which had produced constriction and ultimately occlusion of the canal by the lodgment of foreign bodies within it.

The patient, a gentleman sixty-three years old, of full habit and general good health, had complained for some time of deep-seated pain in the right hypochondrium. Finding himself unable to empty his bowels, he called in his physician, who gave him laxatives and enemata; these proving ineffectual, and the patient's suffering increasing, a consultation was held; the diagnosis of mechanical obstruction was made, and operative interference, beyond the administration of full enemata, was rejected. The constipation persisted, and on the sixth day the patient died quite suddenly in collapse.

On opening the abdomen, the convolutions of the small intestine were found arranged with the greatest regularity in parallel lines in the direction of the axis of the body, those belonging to the lowest part of the ileum lying in the right iliac fossa against the anterior abdominal wall. The peritoncum was injected and covered with a faint exudation, and about a table-

spoonful of reddish serum was found in the peritoneal cavity. The cæcum and colon were distended as far down as the stricture, which occupied a point in the transverse colon between the median line of the body and the cartilages of the right ribs. Beyond this point the colon was contracted and entirely empty.

On dividing the intestine and everting it like a glove-finger, the upper end of the stricture appeared as a rosette about three centimetres in diameter, slightly congested, with an eccentric lumen that would admit only the tip of the little finger, and occluded by three fragments of the endocarp and a pit of an apple. Just beyond the distal end of the stricture were two or three dark submucous collections, the remains probably of interstitial hemorrhages; but at neither end was there any sign of recent hemorrhage or ulceration.

When divided longitudinally, the stricture proved to be nearly one inch long; its canal was tortuous, three-fourths of its wall being formed by the projecting neoplasm, the remaining fourth by a cicatricial tissue occupying the site of the mucous membrane.

Microscopical examination showed the tumor to be of the variety known as cylindrical-celled carcinoma, with an unusually abundant stroma and with firm fibrous prolongations into the sub-peritoneal fat.

#### VESICO-INTESTINAL FISTULA, LUMBO-COLOMOTOMY.

DR. WEIR presented a specimen of vesico-intestinal fistula, for the relief of which, left lumbo-colotomy had been performed. The patient, aged 43 years, was an ice-dealer who had enjoyed good health until June last, when he experienced difficulty in urination. The history which he gave of the trouble, suggested the possibility of traumatic origin. In 1862, while descending a ladder, he straddled one of the rounds, injuring his perineum, and subsequently passed bloody urine. Shortly afterwards a stricture of the urethra was developed, and the operation of external urethrotomy was performed by the late Dr. Krackowizer. He was told that in order to secure the patency of the canal, it was necessary to use an instrument at stated intervals. This he did for a time, and then as usual neglected himself. There was a strong suspicion, from the color of the urine, its fecal odor, and the solid matter discharged, that a fistula existed, communicating with the large intestine; but there was a great deal of difficulty in diagnosing its precise position. Recollecting a case presented by Dr. Krackowizer, in which the existence of such a communication was made out by the injection of ink into the bladder, and its reappearance in the rectum, Dr. Weir determined to resort to a similar expedient. Not wishing to employ ink, in consequence of existing irritation in the bladder, he chose milk. Accordingly, two or three pints of milk were injected into the bladder, while a speculum was placed in the rectum. The experiment, however, was unsatisfactory, as the co-operative expulsive efforts of the patient had been suspended by the etherization resorted to.

By the bimanual examination a tumor was, however, discovered in the left iliac region, and was suspected to involve the upper part of the rectum. The following day milk was again injected into the bladder without the use of an anæsthetic, and was expelled per rectum in a very few moments.

The diagnosis being then reasonably clear that the opening was situated in the descending colon or rectum, the operation of left lumbo-colotomy was performed, Aug. 30, by Bryant's oblique incision.

The man did very well after the operation; his bladder symptoms were markedly relieved, and his intervals of urination lengthened out. Faecal masses

would, however, in the last weeks of his life, escape into the bladder during the night-time. He died with symptoms of phthisis, Nov. 14. At the autopsy there were found tuberculous ulcerations in the small intestines, and some in the large intestine. The small intestines were matted together in the pelvis, and with the thickened adhesions constituted the tumor felt during life. The opening into the bladder, which had an irregular communication with the upper part of the rectum, was capable of admitting the end of the finger.

DR. DELAFIELD presented specimens illustrating

#### DIFFERENT FORMS OF CANCER OF THE STOMACH.

CASE I.—The patient was a male aged forty-seven, who suffered with vomiting and pain in the stomach for the last eleven months of his life. Two months previous to death he vomited blood quite freely, followed by a coffee-ground material. On examination, a tumor was felt through the abdominal walls in the lower part of the epigastric region. At the autopsy the tumor was found to occupy the pyloric orifice of the stomach entirely within the organ, and acted in that position as a ball-valve.

CASE II.—Male, aged fifty. The first symptom, which was pain in the epigastrum, commenced fifteen months before death. Patient never vomited, became cachectic, œdematous, and emaciated. No tumor felt in epigastrum. Liver enlarged. Diagnosis was cancer of liver rather than of stomach. At autopsy there was found a new growth on the anterior part of the stomach, extending outwards into the left lobe of the liver, forming there a cavity through which food penetrated.

CASE III.—Female, aged twenty-eight years. First symptoms, vomiting and constipation, occurred fourteen months before death. No special pain about the region of the stomach. A month before death vomiting ceased. No tumor felt in the region of the stomach. No cachexia. Emaciation extreme. Death by starvation. At the autopsy the stomach was dilated and filled with food. Muscular coat thickened. Pylorus narrowed to the size of a goose-quill. No tumor present. There was a cancerous growth in the submucous coat around the pylorus, extending into the mucous and muscular layers. The points of interest in this specimen were: the age of the patient, absence of any tumor, and extreme contraction following such a small amount of deposit.

#### COMPLETE CONGENITAL DISLOCATION OF THE TIBIA BACKWARDS.

DR. MASON presented a specimen of complete congenital luxation of the tibia backwards, removed post-mortem from the child of a mulatto, who died at the age of one month. Besides this there was an outward dislocation of the os calcis, the scaphoid and anterior portion of the foot being thrown inwards. He remarked that these cases were easily reduced, and with care would remain so.

DR. SAYRE referred to a case in which a double dislocation of that sort had been reduced by him with good result. The child was now four years old, and had perfect motion in the lower extremities.

#### SUBMUCOUS UTERINE FIBROID AND ACTUAL CAUTERY.

DR. POST presented a submucous uterine fibroid, which he had removed by operation two weeks before, from a patient of the Presbyterian Hospital. The patient, aged thirty years, consulted him in October. She stated that three years ago she had a tumor removed from within the vagina. She presented at the vulva a large mass, which could not, on account

of its size, be drawn out. After resorting to various means for its removal, Dr. Post concluded to try the actual cautery. The heated irons were plunged to the depth of four and four and a half inches in different directions. Then with a scissors the accessible parts were cut away, and afterwards a claw-forceps brought the remaining portion of the mass forward, when the pedicle was grasped by the chain of the craseur and the whole removed. The tumor was attached to the posterior lip of the cervix, and weighed a little over two pounds.

#### PERFORATION OF THE APPENDIX VERMIFORMIS.

DR. BRIDGON next presented a specimen of perforation of the appendix vermiformis, with the following history: I saw the gentleman from whom this specimen was obtained in consultation with Dr. Theophilus Steele, of this city; he was of Southern birth, well proportioned, and in the prime of manhood. Two years ago he had an attack of what his medical attendants called inflammation of the bowels, and the trouble on that occasion was principally upon the right side.

His present illness began on Sunday morning, Dec. the 3d. At about 4 A.M. he was awakened by severe abdominal pain diffused all over that part, but described as being most severe around the umbilicus; it was constant, but aggravated at frequent intervals by paroxysms of increased severity; the parts were also tender upon pressure. He had had no evacuation from the bowels, had only vomited once or twice; his tongue was moist and only moderately coated; his pulse was only slightly accelerated, and his temperature normal.

I saw him with the doctor on Monday, December the 4th. His decubitus was dorsal, his thighs slightly flexed, his pulse was a little over a hundred, temperature 100°, expression anxious; his abdomen was distended, tympanitic, and everywhere exquisitely tender, but most so in the right inguinal region; the last mentioned part was thoroughly examined; it was resonant as the neighboring regions, and no tumor of any kind could be discovered by such manipulations as the patient could tolerate. He had no swelling at any of the usual sites for hernial protrusions, and the question arose whether the symptoms were occasioned by intestinal obstruction due to bands resulting from his previous attack of inflammation, or to extravasation through a perforation of the appendix vermiformis, and a due consideration of all the facts led me to adopt the opinion that extravasation, and not obstruction, was the principal factor. The most prominent feature was the evidence of acute diffuse peritonitis, and its sudden invasion—in fact, I think the symptoms of obstruction were wanting; vomiting had only occurred once or twice, and did not recur after the first day. The treatment adopted was the hypodermic use of morphia in sufficient quantity to control pain, local depletion by the application of a dozen leeches over the right iliac fossa, and the assiduous use of hot fomentations; the faithful use of these means availed nothing, the patient rapidly sank into a condition of collapse, and died at 7 P.M. on the 5th—being sixty-three hours from the invasion of the disease.

Autopsy was made sixteen hours after death. Rigor mortis was well marked, abdomen was distended and tympanitic, no tumor could be detected in the iliac region; on making a section of the abdominal walls a large escape of gas, having a strong feculent odor, occurred, and this was followed by a considerable quantity of fluid, stained and mixed with feces; the omentum was adherent to the intestines, which were largely inflated, but the large intestine was more dis-

tended than the small; the convolutions of the lower portion of the ileum were matted together and to the neighborhood of the caecum by recent lymph; on stripping some of this deposit from the ileum ten or twelve inches from its termination, an irregular spot presented itself that was a dark slate color, and looked as if it were in a condition of sphacelus. A subsequent careful examination of this part showed the opposed mucous surface intact.

On removing the caecum, a perforation was found in its appendix, about two inches and a half from its junction with the gut. The perforation was circular, about a third of an inch in diameter, and exposed to view a foreign body which I have left *in situ*. It will be seen that it is impacted near the extremity of the appendix, that it is circular or ovoid in form, and from examination of its exposed surface, and the percussion note elicited by tapping it with the back of a knife, I am led to regard it as a plum-stone.

*Remarks.*—This is the second specimen that I have presented within a year, of the parts involved in fatal perforation of the appendix caeci. The first occurred in the practice of Dr. Hadden, of this city, and had many features in common with the present. In both there was large abdominal effusion, with general diffuse peritonitis, and rapid collapse; in neither were the conservative processes that eventuate in abscess and possible recovery successful. And I think that such an event will always be determined by the empty or full state of the intestine at the moment that perforation occurs. If the escape of feces be exceedingly small, nature may wall it in by abscess; if, on the contrary, it be large, fatal diffuse peritonitis must be inevitable. Certainly, in both of these cases the resources of nature were inadequate; the products of inflammation were broadcast, not concentrated to the immediate neighborhood of the lesion. There was not even the semblance of incipient abscess.

#### NEW YORK MEDICAL JOURNAL ASSOCIATION.

*Stated Meeting, December 15, 1876.*

DR. CHARLES M. ALLIN, PRESIDENT, IN THE CHAIR.

#### PREVENTIVE MEDICINE AND LONGEVITY.

DR. W. DEFOREST DAY brought before the Association certain facts which had a bearing upon the above subject, and of those the more practical and important were the following:

#### RECORDS OF THE BOARD OF HEALTH WITH REGARD TO YOUNG CHILDREN.

Dr. Day, in consulting the records of the Board of Health as Sanitary Superintendent, had found that the condition of young children with regard to life was a most sensitive gauge for determining the presence and effect of deleterious influences. Of the total deaths occurring in the city, the mortality under five years of age, between the years of 1867 and 1874, had been found to vary from 52.99 to 48.81 *per centum*. The mortality, except in epidemics, had not varied very much from year to year.

#### CIRCUMSTANCES FAVORING INCREASE OF MORTALITY IN GENERAL.

Overcrowding was regarded as the sum of all sanitary evils, and an outgrowth of civilization, with its advantages and disadvantages. Insufficient house accommodations produced disease, pauperism, and crime, until vice became second nature, and morality, virtue, truth, and honesty were mere names. New York differed from all other cities in having no true

suburban districts, and the buildings were constructed upon the plan of getting the greatest gain, rather than in consideration of the welfare of the occupants. It was stated that there was not a single tenement-house in the city of New York which had been built with reference to the removal of garbage. The tenement-houses numbered about 25,000, and perhaps the most crying evil among them was the want of proper ventilation. No plan of ventilation had yet been devised which was automatic, which operated independent of intelligent supervision. Such provision for ventilation was the more important, because the habitual inhalation of foul air soon caused an insensibility to its deleterious effects; hence they became prolonged.

#### SMALL-POX AND VACCINATION.

For the prevention of small-pox two things were regarded as necessary: 1. to press vaccination; and, 2. to make the small-pox hospital as comfortable as possible, thus wiping out the dread people might have of entering it for treatment.

With regard to compulsory vaccination, Dr. Day took no positive position, but stated the following: In the city of New York, according to the latest report to the Board of Health, there were four cases of small-pox. In London, where compulsory vaccination was in accordance with the law, the latest report, given at about the same time of the report in New York, noted fifty-three deaths from small-pox. In London, however, revaccination was not practised.

#### DISINFECTANTS.

With regard to measles, scarlet-fever, typhoid and typhus fevers, whooping-cough, and diphtheria, disinfectants were regarded as useful in a certain way. They were valuable in small-pox after the patient had been removed from the room or house; they were valuable in typhoid and diphtheria for disinfecting the discharges—sputa and excreta. They were believed to be valueless, so far as killing the germs of the disease was concerned, while the patient remained in the room; for anything which would kill the germs would also kill the patient.

#### HOSPITAL DEFICIENCIES.

There was no hospital in the city of New York which would receive a case of diphtheria or any other contagious disease aside from small-pox and syphilis. That fact alone contributed largely to the increase of the death-rate, as could be readily understood, and the remedy was apparent.

#### CONTAGIOUS DISEASES AND PUBLIC SCHOOLS.

It was believed that the question of preventing the introduction and spread of contagious diseases in the public schools depended more upon the discrimination and good sense of the people than upon anything that could be effected by legislation. The influence of the physician could be made most powerful in that direction, and he would be able to control certain matters which it would be impossible to reach by legal enactments.

#### MALARIA.

In the year 1868 there were registered 95 deaths from malarial fever; in 1869, 128; in 1870, 213; in 1871, 291; in 1872, 348; in 1873, 282; in 1874, 295; in 1875, 275. About one year ago, at the direction of the Board of Health, a circular was issued to a certain number of physicians, with the view of obtaining information upon the subject. For certain reasons, it became necessary to abandon that method of acquiring information. The plan of writing to every physician who reported a death from malarial fever was then

adopted, and he was asked to give information as to whether the disease was contracted in the city; whether, in surviving cases, it was really malarious or simply a vague malaise and depression that were cured by quinine and change of air; whether it was distinctly periodical. These observations were confined to the city below Harlem River; for above that point malaria was common and undoubted. The result had been that only forty cases had been put down upon the map as having died from malarial fever contracted in New York. The method of obtaining information was imperfect, doubtless, but it was the best that the Board had been able to employ.

#### MAP SHOWING THE DISTRIBUTION OF DIPHTHERIA.

Dr. Day exhibited several maps upon which was shown where every case of certain diseases had occurred, and it was found that diphtheria had not followed the old water-courses in the city, nor had any cases occurred upon made land. It had been found that it occurred most largely in the crowded portions of the city. The exhibit upon the map was based upon fatal cases, believing that there was less liability to error in diagnosis when the case proved fatal than when recovery took place.

Dr. E. G. LORING, in remarking upon the subject of sewerage and traps, referred to by the author of the paper, called attention to the use of peppermint essence as one of the most valuable and certain agents that could be employed in detecting whether, in any part of a house or sewers connected with it, there was any defect in the pipes leading from the water-closets. Pour an ounce or two of the essence into the basin, let a gush of water fall upon it and carry it through the pipes, and if there was any leak it could be detected by the presence of the odor of peppermint in the room, or closet, or sewer near where the imperfection in the conducting pipe existed.

After some remarks by Dr. M. Morris, and a vote of thanks to Dr. Day for his address, the Association adjourned.

#### MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Adjourned Stated Meeting, January 8, 1877.*

DR. JOHN C. PETERS, PRESIDENT, IN THE CHAIR.

#### REFLEX-MOTOR SYMPTOMS.

DR. EUGENE DUPUY presented his views regarding the physiological pathology, diagnosis, and treatment of such reflex-motor symptoms as paralysis and contractions. The paralysis and contractions were regarded as reflex symptoms because they had been developed by reflex processes; that the primary disease was not in the nervous centres, but at the peripheral nerve terminations.

Brown-Séguard had attempted to explain the phenomena by the theory that the paralysis was due to contraction of the blood-vessels; that the contraction, after a time, produced an alteration in the tissue of the spinal cord; hence paralysis followed. That theory had not only been questioned, but even the existence of reflex paralysis had been disputed. It was regarded necessary, therefore, to first establish the claim the disease had to a recognition. Dr. Dupuy regarded its existence as undoubted, and maintained that reflex paralysis and contraction belonged to the same category, and that the motor symptoms embraced both conditions. It was stated that almost every part of the body, including the nerves of special sense, might be affected by reflex paralysis.

There were certain cases of the disease following irritation of the nerves of the pleura; Lépine had reported a number of cases in which hemiplegia had occurred in consequence of pneumonia; contraction had been produced by strangulated hernia, sometimes on one wrist, sometimes in the other, and generally upon the opposite side; paralysis had also followed disease of the kidney; renal calculus had produced paralysis, which was relieved as soon as the concretion had passed; the reflex disease had been seen associated with cataract; and genital irritation was a prolific source of such phenomena. In the cases reported by Prof. Sayre, the contraction had manifested itself quite uniformly in the muscles of the legs and arms. As preliminary to giving his own explanation of the reflex phenomena, Dr. Dupuy referred to the different theories that had been advanced. Jackson and Weir Mitchell had brought forward the theory of exhaustion; the nerve-centres and the nerves themselves became exhausted; therefore, paralysis ensued. Dr. Dupuy did not accept that theory, for, when exhaustion produced paralysis, it was due to loss of irritability, and, when the nerve-centres had recuperated, the same phenomena might be reproduced, and would be followed by the same result. That was not observed in reflex paralysis and contractures.

McDonnell, of Dublin, had explained the disease on the ground of inhibitory action, and conceived that the nervous centres were placed in a state of paralysis suddenly. His experiments had been made upon snakes, and he had found that when the animal was struck upon the tail it instantly became stiff and apparently dead.

Another explanation had been given by a German, who maintained that organic changes took place in the spinal cord, at a point corresponding with that at which the nerves supplying the affected part were given off, the nerve itself being healthy. That theory had been deduced from experiments in which the sciatic nerve had been cauterized, and the cauterization had been followed by central changes, spots of softening, etc., at a level with the origin of the nerve. Dr. Dupuy, as well as other experimenters, had been unable to obtain the results claimed by the advocate of the above theory, and he was unable to account for the different results obtained by different experimenters. The results as reported were believed to be undoubted, but their explanation was not clear.

Dr. Dupuy believed, however, that it was possible to explain the phenomena of reflex paralysis and contractures, and referred the cause to dilatation of blood-vessels, with subsequent arrest of the nutrition of the nerve elements; that is, peripheral irritations produced changes in the nerve-centres which regulated the blood-supply. The change in the central blood-vessels produced by irritation of the peripheral extremity of a sensitive, even a motor nerve, was of dilatation, and not a contraction. Contraction was only fugitive, and the dilatation might be above or below, as well as at the point at which the nerves took their origin, and was lasting. The first effect of the peripheral irritation was contraction; but that continued only for a very short time, and then ensued the dilatation, appearing gradually, and increasing until pulsation ceased, when the blood in the veins and arteries would appear of the same color. Such were the phenomena observed in the vessels of the pia mater when the kidneys were irritated; and when the phenomena were produced in the spinal cord, sufficient blood was retained to sustain life, but not to prevent changes in nutrition such as might give rise to impairment of the organic structure. Dr. Dupuy de-

nominated the condition as paralysis due to fatigue of the blood-vessels. The fact that cure did not follow within a short time after the removal of the irritation did not show that the disease was not reflex, for the tendency was to produce changes which could not be removed within twenty-four hours; and, besides, there was the habit of the disease to be overcome.

Dr. JACOBI remarked that when the term reflex paralysis first appeared in medical literature, he was not inclined to accept the theory of the term itself. The theory had been, and was, that paralysis was the result of external irritation. He was prepared to admit and was able to understand how peripheral irritation could be the cause of central irritation; he could readily believe that contractions or convulsions might result from external irritation, but he was not able to understand how paralysis could be the immediate result of external irritation. He had supposed that we were to look for some central change in the shape of irritation which gave rise to the paralysis following external irritation. Dilatation of the blood-vessels was due, not to paralysis, but irritation of the sympathetic; dilatation of the central blood-vessels occurred as the result of irritation of the peripheral extremities of the vaso-motor nerves, and the paralysis of the various parts of the body resulted secondarily from the irritation developed by such dilated blood-vessels. He was inclined to believe in paralysis due to irritation caused by a condition which was produced by a primary peripheral irritation, and not in paralysis as being the immediate result of external irritation.

Dr. MARY PUTNAM-JACOBI remarked, that by the terms of the question reflex paralysis it was to be supposed that an irritation went to the centre, but from the centre nothing came; the paralysis must terminate in the nerve-centres. She regarded the theory advanced by Dr. Dupuy as one to be carefully considered, for he attributed the paralysis not to the effects produced by compression of the nerve elements by the dilated blood-vessels, but rather to an arrest of nutritive changes between them on account of the stasis of blood. She asked the question, if the paralysis occupied several months, did it not remove the cause beyond mere vascular conditions?

Dr. SPITZGA inclined to the belief that central lesion was the cause of the paralysis.

Dr. SAYRE, although making no pretensions in the way of giving scientific and incomprehensible explanations, was not able to understand how, in those cases in which total and rapid relief followed removal of the peripheral irritation, the paralysis could be due to organic changes occurring in the nervous centres.

Dr. JACOBI believed that a large majority of the cases reported by Dr. Sayre were such as manifested no paralysis at all, but rather a protracted convulsive movement; he therefore believed that the cases went to the support of his theory concerning the real cause of phenomena.

Dr. SAYRE remarked that symptoms, both spastic and paralytic, had been present in his cases, and that both had been removed by a removal of the external irritation, commonly some form of genital irritation.

Dr. OTIS related a case which might, perhaps, add something. A patient had loss of sensibility of the right leg, and it had existed for several months. He was found to be suffering from several urethral strictures, not close, and, during the examination and subsequent to it, he suffered pain in the leg which had been so long without sensation. An operation was made, the stricture relieved; the sensibility of the leg was almost at once restored, and had remained complete.

Correspondence.

DISLOCATION OF THE PATELLA.

TO THE EDITOR OF THE MEDICAL RECORD.

STR:—Upon reading Dr. Dougherty's account of a recent and rare form of dislocation of the patella, published in the last number of the Record, I am impressed with the belief that the following might be of interest in connection with the same. On the evening of October 30, 1874, I received a telegram from Chester, Orange Co., to immediately visit Matthew Doyle's house, and take charge of a "fractured thigh."

Doyle had sent for Dr. C. P. Smith, of Chester, and the doctor being absent, the messenger telegraphed for me.

On arriving at Doyle's, I found a boy aged nine years lying upon his back in bed.

The right limb was the one injured, and on inspection presented a peculiar appearance. The deformity consisted in a great conoidal prominence over the knee-joint, which I at once recognized as the patella set up on its inner edge. The leg was not in a condition of "extreme extension," but seemed flexed from a direct line, possibly a few degrees.

After making sure of the character of the injury, and to relieve the strain upon the patella preparatory to reduction, I seized his ankle in my right hand, and raised it from the bed; then I placed my left hand over the patella and grasped the knee; then by depressing the knee forcibly with one hand, and raising the heel with the other, I found it a very easy matter to rotate the patella to its normal bed.

Of course in a case occurring in a strong adult it might be much more difficult to reduce, but Doyle's case did not detain me in the house to exceed five minutes all told.

The boy had injured himself while wrestling with a playmate, and being thrown violently down, and the limb being so distorted, his friends at once believed that he had sustained a fracture of the thigh.

I have never seen the boy since the night upon which I reduced the dislocation, but Dr. Smith assured me that he directly recovered the perfect use of the injured limb.

Respectfully,

WM. B. BRADNER.

WARWICK, ORANGE CO., N. Y., JAN. 1, 1877.

CINCHO QUININE.

TO THE EDITOR OF THE MEDICAL RECORD.

STR:—In your issue of 6th inst. Dr. J. B. Mattison records his experience in favor of cincho quinine as a substitute, or rather superseder of the old and tried sulphate of quinine. As my experience is at variance with his, allow me to ask you "*Audi alteram partem.*" When I consider the amount of advertising which cincho-quinine has had and the number of recommendations and puffs obtained for it, I am quite prepared to believe, quoting Dr. M., "that nothing is needed, *sane clinical evid. nec,* to prove that it possesses, in large degree, the valuable properties of the universally used cinchona." The italics are mine.

Induced by advertisements, I was induced in the spring of 1875 to give it a trial in malarial cases. It was given sometimes as a powder with white sugar, but mostly in solution. It is certainly much less bit-

ter than quinine, and in any dose given did not produce symptoms well known under the term cinchonism. I gave it in the same way and in the same doses by weight, as I had found quinine promptly antiperiodic. Contrary to Dr. M.'s experience, I found it produced some gastric disturbance in nearly all cases, and was much complained of in about one third. This would not have been a great disadvantage had it done the work, but it did not at all satisfactorily. It had a perceptible and marked effect upon the paroxysms; but this was only partial, no complete, and in a few days they would begin to recur. I now resorted to double my usual doses, with the effect of producing very disagreeable and rather prolonged gastric disturbance in a large majority of cases. The check given was now more decided, but each case was about sure to relapse in a week or ten days, having been only indifferently well in the meantime. I was led to believe that it was *absolutely unreliable* for radical cure, and quite *inferior to quinine* in efficacy. I hence abandoned it for quinine in adults; but, on account of the taste, preferred cincho-quinine for children. This, too, I soon found it expedient to abandon for reasons the same as in adult cases. I think, however, resort to it for economic reasons will be "penny wise and pound foolish."

As a tonic, did not give it an extended trial; but, from *a priori* reasons, chiefly its producing gastric disturbance, I would expect little. If a cheaper substitute for quinine be wanted, we have sulphate or muriate of cinchona, available at from one-third to one-half the price of cincho-quinine. Is the latter any better than any of the simple bitters?

Respectfully,

ALEX. HAMILTON.

288 MADISON ST., N. Y., Jan 8, 1877.

INACCURACY OF GLASS GRADUATES.

TO THE EDITOR OF THE MEDICAL RECORD.

NEW YORK CITY, January 3, 1877.

STR:—Having occasion some time ago to visit a glass manufacturer's establishment, I observed whilst there, a workman marking the lines on, or rather graduating glass measures, by holding them against a revolving wheel, and to my surprise without any method of adjusting the lines, excepting such as his own judgment would indicate. It appeared at the time so absurd, that it elicited the question, "Is it possible to mark them in that way, so that they will measure correctly?" On which he replied, that he was so accustomed to that kind of work, that he could mark them near enough for all practical purposes.

At that time I purchased a half ounce graduated measure, cut so as to measure half drachms.

Since the adoption of the Metrical System by the N. Y. Co. Med. Soc., I have tested the measure with distilled water at the temperature of 60°, and find it to read by weight as follows:—

The following are the weights the measure ought to give in grains.	The following are the weights the measure did give in grains. . .
f ʒ ss . . . . .	28.48
f ʒ i . . . . .	56.96
f ʒ jss . . . . .	85.44
f ʒ ij . . . . .	113.92
f ʒ iijss . . . . .	142.40
	38.57
	66.54
	93.39
	123.44
	151.52

The remaining graduations were equally inaccurate.

Very truly yours, etc.,

THOS. H. HOLGATE, M.D.

DEATH FROM CHLOROFORM, IN WHICH ALL THE USUAL PRECAUTIONS WERE TAKEN TO GUARD AGAINST IT.—A man, aged thirty-three years, was admitted into the Charing Cross Hospital (London), Dec. 20, with a recent and irreducible, although not strangulated, hernia. After the usual efforts at reduction in the warm bath, etc., the administration of chloroform was advised. Dec. 22. There had been no vomiting. From the time of his admission until his death the patient was kept upon liquid diet. The *Brit. Med. Journ.* (December 23, 1876), in giving the details of the mode of death, says: On Friday, he had his half-pint of beef-tea at one o'clock, and was ordered to have no more food after that hour, as the chloroform administration was fixed for the evening. The man lay quietly in bed, and did not complain of exhaustion, but asked to have as little chloroform as might be, saying that he was not a strong man. He had been a publican, but there is no evidence as to his habits. Shortly after eight o'clock, the administration was commenced by one of the assistant resident medical officers, who was quite accustomed to the duty. The patient lay in bed, loosely clad. The heart was examined by the stethoscope, and considered to be normal, and no stimulant was administered. The anæsthetic was given on folded lint, one-half drachm being poured on at a time. At the end of four or five minutes, when the fifth half drachm had been poured out, the taxis not having been commenced, and there having been no marked struggling, the face suddenly became livid; and the administrator, having his finger on the pulse, noticed it to become feeble, at the same time that respiration became slightly stertorous. The chloroform was at once removed, a pillow was placed under the patient's shoulders, so that the head fell rather backwards, the tongue was drawn forward by forceps, and artificial respiration, by Sylvester's method, was commenced. As soon as possible, two ounces of brandy, with warm water, were injected into the rectum; the

chest was also flapped with wet towels, and the extremities rubbed and warmed. The patient, however, gave no sign of rallying, and ceased to breathe in the course of three or four minutes from his seizure. Later on, faradism was applied to the phrenic nerve, and artificial respiration was continued for an hour, but without result. At the post-mortem examination, the lungs and brain were found congested. The heart was large, and its right cavities were full of dark blood. The right ventricle was noted to be thinner than normal, and was overlaid with fat. There was no naked-eye evidence of fatty degeneration, and the microscope was not used. The liver was fatty. An inquest was held, and a verdict returned to the effect "that deceased died from the effects of chloroform, but that it was properly administered."

PREVENTION OF AFTER-PAINS.—DR. Le Diberder (*Ann. de Gynécolog.*) believes that ergot suitably administered has the power of preventing after-pains. He gives half a drachm in divided doses directly after the expulsion of the placenta, with the object of bringing about a firm and consistent contraction of the uterus in place of the alternate contractions and relaxations to which he says after-pains are due. The *Dublin Med. Press and Circ.*, in commenting upon this statement, calls attention to the opinion of Sir Charles Locock, that after-pains were due to the retention of coagula, and that firm manual pressure upon the uterus to promote their expulsion was never followed by after-pains.

A WELL-DESERVED COMPLIMENT TO DR. JAMES O. POND.—At a stated meeting of the New York Academy of Medicine, held January 4, 1877, a committee, consisting of Drs. Wm. Detmold and G. M. Smith, presented the following preamble and resolutions, which were unanimously adopted:

*Whereas*, Dr. James O. Pond, having attained the age of eighty six years, and having concluded a service of twenty-nine consecutive years as Treasurer of the New York Academy of Medicine, has declined to be a candidate for re-election; therefore,

*Resolved*, That the Academy desires to place on prominent record its warm appreciation of his long and faithful interest in the Association.

*Resolved*, That as one of the founders of the Academy in 1847, as one of the incorporators in 1851, as Treasurer since 1848, he has, from the inception of the Association to the present moment, manifested a zeal in the welfare of the Society which has contributed largely to its success.

*Resolved*, That in the onerous duties of the Treasurership he has always held the unbounded confidence of the Academy, and his example for courtesy, efficiency, and integrity, will ever remain as a model for future incumbents of the office.

*Resolved*, That the Academy wish him length of years, with health to enjoy the close of a long and honorable career.

*Resolved*, That a copy of this preamble and of these resolutions be entered in full on the minutes of the Academy, be published in the medical journals of this city, and that a suitably engrossed and authenticated copy be presented to Dr. Pond.

S. S. PURPLE, M.D., *President*.

W. T. WHITE, M.D., *Secretary*.

THE CONDITION OF OUR HOSPITALS AND CHARITABLE INSTITUTIONS.—At the recent monthly meeting of the State Charities Aid Association, the Committee on Children reported that the Infants' Hospital on Randall's Island was filled with mothers having children under three years of age, there being no restriction to

the length of time these women can remain, provided they take care of their own children. Some employment should be provided for such women, as they are idle a great part of the time. Fifty-one infants are boarded out in Westchester county. Among these the death rate was lower than at Randall's Island. There were one hundred and seventy-nine children at the Idiot Asylum. The building was scrupulously clean, and the children were well cared for. The schools re-established in October were also in a satisfactory condition. The Committee on Out-door Relief reported that, owing to the representations of its sub-committee concerning the great evil connected with station-house lodgings, the Police Commissioners had closed the station-houses on the 5th of November. In order to provide for worthy persons in need of shelter at night, several gentlemen of this committee, in connection with others not members, had formed the Night Refuge Association, which, although open only a few nights, was now receiving nearly one hundred and fifty lodgers nightly.

The Kings County Visiting Committee reported a few of the repairs which were most needed in the Lunatic Asylum building. The walls and ceiling of many of the rooms were black and dirty; the bread was sour and dark colored, and since this is the one article of food given in liberal quantities, its bad quality is especially to be regretted. The diseased and imbecile occupants of the basement of the Female Almshouse have been removed to another building. Complaints of sour bread and green potatoes were still received; the inmates complained of cold, and the laundry arrangements were found very poor. An organization for out-door relief, with full corps of visitors, has been formed.

**OFFICERS OF NEW YORK PATHOLOGICAL SOCIETY.**—The following officers have been elected for the ensuing year: Dr. E. G. Janeway, President; Dr. E. L. Keyes, Vice President; Dr. George F. Shrady, Secretary; and Dr. John B. Hinton, Treasurer.

**THE RAILWAY CHLOROFORM TRAGEDY.**—The coroner's jury brought in the following verdict concerning the recent death by chloroform in Rahway: "We believe that the death of Walter E. Lewis was caused by the administration of chloroform for the purpose of extracting a tooth, and that it was administered by Dr. Warren E. Westlake without a proper examination of the patient; and we consider it gross negligence on the part of the said Dr. Westlake in not making the said examination, and not knowing the nature of the anæsthetic used."

**THE BROOKLYN INSANE ASYLUM.**—The project concerning the foundation of the Brooklyn Insane Asylum is beginning to take a definite shape. In order to take off the obnoxiousness which associates itself with the name of an Insane Asylum, it is proposed that the institution be known as the Hospital for Nervous Diseases.

**ALBANY MEDICAL COLLEGE.**—As might have been expected, the Common Council of Albany has refused not only to allow the faculty of the Albany Medical College the use of their building free from rent, but has directed the Corporation Counsel to take the proper measures to insure the payment of all arrearages, or turn over the property to the city authorities without delay.

**THE SPREAD OF DISEASE.**—Dr. Cornelius Fox, medical officer of health, London, gives some remarkable illustrations of the way in which infectious diseases are spread: "In one case a publican's wife attended to her children ill with scarlet fever, and to

her husband's customers with equal assiduity and impartiality. As a consequence, the disease soon ran riot throughout the neighborhood. Another instance was the refusal to close temporarily a village school where measles was prevalent. In one case small-pox existed in a restaurant, the characteristic odor of the disease pervading the bar where men stood drinking. Again, a tailor made clothes for people while enteric fever prevailed in his house, and thus distributed the infection. Several other instances are given by Dr. Fox, all of which demonstrate the need of granting greater powers to sanitary bodies."

**THE AMERICAN BI-WEEKLY.**—*The American Medical Weekly*, of Louisville, Ky., has been changed to a bi-weekly, with an appropriate title. The editor, Dr. E. S. Gaillard, gives very good reasons for the course pursued, and presents his readers with a model journal of its kind. The present issue is so much of an improvement upon the older ones in its make-up, character, and variety of contents, that it cannot fail to give universal satisfaction. We cordially wish Dr. Gaillard success in his new enterprise.

**BIRTH, MARRIAGE, AND DEATH STATISTICS.**—The Board of Health has sent a circular to clergymen, magistrates, physicians, nurses, etc., requesting them to comply with the sanitary code in making correct returns of births, marriages, and deaths that come under their direction. Those who fail to comply with this regulation are to be promptly prosecuted, and if convicted will be subject to a fine of from \$10 to \$200, or imprisonment in the county jail for a term not to exceed thirty days.

**YELLOW FEVER IN SAVANNAH, GA.**—*The American Bi-Weekly* asks: "Can any one in this city give any information as to the facts of the yellow-fever epidemic of 1876?" Pending an answer we would respectfully refer to the report on that subject by Dr. Octavius A. White, in *THE MEDICAL RECORD* for Jan. 13, page 27.

**DEATH OF HERMANN ALTHOF, M.D.**—Dr. Althof, a distinguished Ophthalmologist of the city, and one of the Surgeons to the New York Eye and Ear Infirmary, died of erysipelas, on Sunday, January 1<sup>st</sup>, after three days' illness, aged 41 years. At the funeral, eulogies were pronounced upon the deceased by Drs. A. Jacobi and Edward Curtis. His remains were interred in Greenwood.

**TETANUS AND HYPODERMIC INJECTION OF MORPHINE.**—A case of death from tetanus following the hypodermic injection of morphine is reported in a recent number of the *Lancet*, Dec. 16, 1876.

**TO DECOLORIZE TINCTURE OF IODINE.**—Rub into it a crystal of hypo sulphite of sodium.

**TYPHOID FEVER** is steadily subsiding in Paris.

**HOMEOPATHIC MEDICAL COLLEGE IN LONDON.**—Steps are being taken for the establishment of a Homeopathic school in London.

**THE ORIGINATOR OF THE SO-CALLED BANTING SYSTEM.** Mr. William Harvey, of London, is dead.

**ARTIC EXPEDITION AND SCURVY.**—And now an attempt is being made to prove that lime-juice has no special effect in the prevention of scurvy.

**THE CLINIC.**—Dr. Roberts Bartholow, of Cincinnati, succeeds Dr. Longworth as editor-in-chief of this journal.

**SOLVENT FOR SALICYLIC ACID.**—Take of salicylic acid  $\frac{5}{8}$  ij.; sol. acetat. ammon.  $\frac{5}{8}$  ij.; and water  $\frac{5}{8}$  vi. M. One ounce of this solution contains 15 grains.

## Original Communications.

## ON SOME CONDITIONS, PHYSICAL AND RATIONAL, IN EFFUSIONS OF THE PLEURA.

CONSIDERED WITH REFERENCE TO THORACENTESIS, FOLLOWED BY AN INQUIRY INTO THE CAUSES WHICH HAVE PRODUCED SUDDEN DEATH AFTER THIS OPERATION.\*

BY BEVERLEY ROBINSON, M.D.,

SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL (DEPART. OF THE THROAT), ONE OF THE PHYSICIANS TO CHARITY HOSPITAL, NEW YORK.

## PART I.

THE great value of thoracentesis in the treatment of pleuritic effusions was admitted by almost all practitioners of medicine, when a few cases of sudden death, occurring within two years, either during, or shortly after tapping the pleura, has given to this procedure fresh interest, and made the time and opportunity of operation an eminently debatable question. From the period Trousseau, in France, and Bowditch, in the United States, had brilliantly inaugurated new methods of puncturing the chest-walls to that auspicious moment when Dieulafoy, Potain, and Traube had employed, with entire success, the improved aspirator, in multiple cases of pleuritis, there were continual accessions to the ranks of those who willingly performed thoracentesis. There were of course detractors from the operation, as there are, and always will be, from all advances in medical and surgical science. Many objections were made to it, many limitations assigned, many dangers pointed out. By degrees, however, opponents, contra-indications, and risks disappeared, until, finally, not a few among us held the conviction, that aspiration could be made with almost perfect safety in all effusions into the chest, and usually with immediate and beneficial results. Again we are called upon to consider the issues involved, and to determine how far, with our actual knowledge, we are justified in reporting thoracentesis to be a satisfactory operation, in view of its probable and possible results.

In order to estimate this subject judiciously, but briefly, I shall scrutinize with care only those propositions which appear to contain mooted points. Those questions which have been decided already by the united weight of recognized authorities I shall refer to in a few words, and merely when the sequence of my remarks requires it.

*a.* Thoracentesis should be performed so soon as practicable, *in all cases*, when there is imminent danger to life from the presence of a pleuritic effusion. The indication to operate, under these circumstances, is so evident and imperative that the unanimous testimony of the profession has endorsed its absolute propriety, and no argument is used to strengthen an unassailable position.

*b.* This operation must be made without delay, *in all cases*, when the effusion is very large. And this rule, too, is absolute, and is in no wise invalidated—either by the nature of the liquid contained in the pleural cavity, or the time it has taken to form. Whilst I hold the second rule enunciated to be true without

limitation, such is not an universal opinion, and needs, in consequence, a fair presentation, so as to make it generally acceptable. I shall first consider those instances where the effusion is of serous or sero-fibrinous nature, has been formed by slow degrees, and where the functional troubles are insignificant. These are not the cases which cause alarm. Frequently they remain undetected, so slight are the respiratory troubles which they occasion. And when, by reason of persistent cough, or febrile disturbance, rather than by due appreciation of the consequences of this condition, a patient thus affected consults a physician, the intra-thoracic effusion is too apt to be slighted. Because it does not visibly and greatly interfere with accomplishment of normal function, danger is not thought of, and mild therapeutic measures are continued. And yet these latent cases of pleurisy are precisely those in which the effusion often reaches the highest point possible, and against which we should be most on our guard. I have seen the lung on the affected side pressed against the vertebral column, the liver and spleen pushed far down into the abdominal cavity, and the heart displaced to a very considerable degree. Under these circumstances many sudden deaths have been recorded by Cruveilhier, Chomel, Aran, and others. These facts were for a time ignored, or flatly denied, owing to a false impression which existed, that simple pleurisy never leads to a sad termination. This erroneous law was first promulgated by Louis. And he and many of his disciples believed idiopathic pleurisy to be ever a mild disease, attended with no risks. Great credit is, therefore, due to Trousseau for having demonstrated conclusively the errors into which Louis had fallen. Numerous autopsies made by him and others have conclusively shown that fatal results are directly occasioned by an excessive pleuritic effusion. These deaths were due to syncope, or to asphyxia. Whenever death took place from the first of these causes, the heart was found, upon opening the chest-walls, considerably displaced from its normal position, and the aorta and other great vessels turned at right angles, or twisted upon themselves. With the circulation thus mechanically obstructed, it is readily understood how even a slight effort, or emotion, might lead to complete and sudden arrest of vitality. I should also cite under this head a few cases where cardiac or vascular thrombosis have been found. And we can readily appreciate in a disease, where hyperinosis is common, the great liability to the formation of these coagula. Whenever death has resulted from asphyxia, the fluid, after completely compressing the lung of the affected side, had pushed aside the mediastinum and encroached so much upon the lung of the other side as to leave no portion of organ in which hematoxis might be adequately performed. In these latter days, pneumonia serosa (Traube) has also explained several cases of sudden death. And at the autopsy the lesions of acute oedema have been found in the lung of the non-affected side. If new sudden deaths do frequently take place in the natural course of a pleurisy of latent type, where the effusion has become very large, and if the post-mortem conditions distinctly show that the presence of fluid in the pleural cavity on either side has been a direct, efficient cause of their production, are we at all justified in delaying to perform an operation which shall surely ward off such occurrences? Evidently not, unless the operation itself be dangerous or objectionable. And this is *not* true, as will be proven further on. Again, if it be admitted that our second law holds good *a fortiori*, it is apparent if the effusion be formed

\* Read before the New York Academy of Medicine, January 4th, 1877.

more rapidly, and the functional troubles are considerable, or if the liquid be purulent in character, there is still more urgent necessity to rid the patient of it by a similar operation. What then are the physical signs which may be relied upon as pathognomonic of effusion into the pleural cavity?

Formerly it was deemed an easy matter to determine the existence of a pleural effusion, and more particularly was this supposed to be true when the quantity of liquid was considerable. And whilst we were well aware how little rational signs could be depended on to give us accurate knowledge in this matter, in auscultation and percussion it was believed we had means at our command which would enable us to declare positively whether or not fluid is present, and, further, what the amount of it is. Since the publication of an exhaustive paper by M. Bouilly,\* entitled "Recherches upon the Relations which exist between the Signs of Pleurisy and the Quantity of Effusion," I have been led to believe that one is frequently induced into error; that it is difficult to draw correct inferences from one patient to another, or with the same patient and same signs to count absolutely upon like presence, nature, and abundance of liquid in the pleura. In fact, there are examples where perfect certainty can only be established by an exploratory puncture made with a capillary needle. When, however, this method is opposed by the views of the attendant physician, upon what physical signs may we rely most securely to make known the nature and limit of the thoracic contents? Are all essential? Or may a few be taken with equal guaranty, though others be absent? To this it can now be answered categorically, that if two be made out with precision, the rest are relatively unimportant, and without these we must remain in a state of uncertainty. These signs are, first: *absolute dullness over the anterior portion of the chest, except perhaps under the clavich*, where a note of high, tympanic pitch may be detected.

Dullness existing in the chest laterally, or posteriorly, may be found united with loss of thoracic vibrations, and exaggerated development of one side of the chest may be present, and yet may be due to the existence of a malady other than pleurisy, with effusion. Such cases have been observed by Dieulafoy, Dechambre, Hénoque, Sée, Martineau, Tardieu, and others. And, on the other hand, Dr. Gueneau de Mussy† has pointed out that in certain instances of effusion the whole of the affected side may give a tympanic sound on percussion. He has even seen a case where this sound succeeded to dullness, although the stethoscopic signs pointed to the existence of liquid. In his estimation, the increased resonance is due to diminished tension of the thoracic wall which renders it more vibratile.

Second: *Complete absence of respiratory, or vocal sounds, either healthy or morbid, in an extent corresponding with that where absolute dullness is present*. If these two physical signs, then, be discovered in the region mentioned, not only may we affirm most positively the existence of effusion in the chest, but indeed of an *abundant* effusion.

The other physical signs made known by palpation, inspection, mensuration, and auscultation may, or may not exist; but, in any event, they are not of equal value with the preceding, nor do they, if present, *always* lend additional assurance of accuracy of diagnosis. Let us now suppose that the existence of fluid is certain, and its quantity is approximately

known, it may be of importance to determine what the nature of it is, whether of serous, or sero-fibrinous, or purulent nature. Formerly it was held, when the effusion had persisted several weeks without notable diminution, and to increased duration of disease at this height were added such symptoms as high fever and intense pain, great and progressive emaciation, with proportionate loss of power, the diagnosis of a purulent exudation was rendered probable. This opinion became much more affirmative if œdema, localized to the affected side, developed itself, and a diagnosis of purulent effusion was made, without much regard to the extent of the subcutaneous infiltration. It might exist over one entire side of the thoracic cavity, or it might be manifest upon and limited to small areas. In either case the diagnosis was equally positive, and almost invariably a puncture or incision on that side of the thorax justified its wisdom. According to our latest information on this subject, the sign just mentioned, viz., localized œdema, is not altogether reliable, inasmuch as it may exist in a recent attack of pleuritis, and yet on puncture a sero-fibrinous fluid be let out.\* Whilst, however, œdema of the chest-wall, when it exists, is a good sign of purulent effusion, as it is not always present, and we may perfectly well have a purulent exudation in the chest without it becoming manifest, it is very desirable to be able to recognize such cases.

Within a brief period some very valuable clinical and experimental researches have been made upon this point; and, in view of their great interest, we shall briefly refer to them here. Hitherto it has been the accepted belief that auscultatory signs which result from different kinds of fluid in the pleural cavity are absolutely similar, or, at all events, that the most acute and cultivated ear is unable to impose characters by which, in the transmission of sounds, their separation may be made. This opinion is altogether opposed to the conclusion arrived at by Prof. Bacelli,† who endeavors to show that the phenomena made known to us by auscultation vary considerably according to the nature and character of the fluid contained in the pleural cavity. He gives, at the end of his memoir on this subject, illustrations which make it evident that the thinner and more homogeneous the fluid is, the more readily vocal vibrations are transmitted.

And, further, that in direct proportion with the fluidity of the liquid, the vibrations are louder. It was also found that sounds were more easily conducted as the ear of the listener approached the base of the liquid; whereas towards its superior surface, it was at times stated that neither bronchial breathing nor loud talking could be heard. Fluids, containing blood, fibrinous flakes, or pus corpuscles, are bad conductors. A wholly purulent fluid is the least favorable to its audition. Other liquids containing granular bodies, fat globules or other bodies *not* fibrinous, transmit vibrations barely as well as hydropic fluids.

One recorded instance appeared for a brief period, however, to invalidate these results. In a case where the presence of liquid was manifested by the ordinary percussion and auscultatory signs, and vocal and respiratory vibrations were distinguished by the observer, a puncture of the chest was made, and a liquid of purulent appearance was evacuated. Fortunately, a microscopical examination of the fluid was made shortly after the operation was performed, and the pus corpuscles were seen to have undergone fatty

\* Archives Générales, March, April, and May, 1876.

\* Traube, quoted by Fraentzel, Ziemssen's Cyclopaedia, Vol. IV., note at foot of page 636.

† Berliner klinische Wochenschrift, May, 1876.

degeneration. Further, the excessive number of fat globules completely disappeared when ether was added.

This case rather adds to the value of Dr. Baccelli's discovery, inasmuch as "aphonic pectoriloquy" may thus bear witness to a molecular change in the fluid, which may influence the prognosis and treatment. The physical law which governs this transmission of sounds in endo-pleural liquids would seem to be quite opposite to what it is in the case of gases. For, in proportion as the liquid is more dense the sound waves diminish in intensity. Moreover, it has been remarked if the liquid be composed of elements of different nature and density, the line of transmission of sounds is not direct, but is considerably refracted. These facts are of manifest importance whenever it is a question of determining the contents of a chest prior to thoracentesis. There are occasions, however, when auscultation and percussion fail to give us satisfactory data, and when, in order to have absolute certainty of the existence of liquid, we shall be obliged to employ an exploratory puncture. Now, as I hope to show, due care being exercised that a puncture with a capillary needle is free from risk, it is permissible to inquire here, whether, upon examination of a portion of endo-pleural fluid, there be not other signs, besides the fact of its serous or purulent nature, which will afford us useful knowledge, and if not in diagnosis, at least in prognosis. Practical investigations have already been made on this subject, and the conclusions arrived at are most valuable.

For both researches and deductions we are indebted to Dr. C. Méhu.\* This distinguished chemist has rendered manifest the importance of estimating exactly the proportionate amount of dry residuum which is left by the complete evaporation of a given amount of fluid. If this quantity exceeds 50 grammes to 1 kilogramme, and if, shortly after the time of the operation, the liquid becomes a consistent mass, we may affirm with confidence that the pleuritic attack is an acute one. And, further, that the greater the proportion of fibrine, the more probable it is that the patient will speedily and thoroughly recover his usual health.

Practically the gravimeter has been found of the greatest use in determining the quantity of fibrine in different liquids. Whenever this instrument is employed in a liquid of the temperature of 15 Centigrade (58° Fahr.) or a density above 1.018, if the liquid rapidly solidifies the case will tend towards a cure at an early date. Whenever the quantity of fibrine either remains of small amount, or there is none present, the prognosis is always grave.

*c. Thoracentesis should be performed in moderately large effusions.*—This proposition will be admitted by the great majority of practitioners, if the effusion be purulent.

Whenever the effusion is of serous, or sero-fibrinous nature, it is still open to debate. Many there are who, acknowledging in part the benefits derived from thoracentesis, will say puncture is admissible and even advisable under these circumstances, if absorption of liquid be long delayed; for we are aware the lung is then exposed to many contingent accidents. It may be bound down by old adhesions, which will prevent it from expanding again to its former capacity. It may become the seat of caseous pneumonia; or military tubercle may develop itself in its structure. Besides, they recognize that the chest-walls may become contracted if old exudations be allowed to form and remain unabsorbed. And then they admit that even

with moderately large effusions, if the effusion remains stationary in the chest for several weeks, the duration of the disease must of necessity be greatly prolonged. For one of two conditions will very generally be present: either the pleura costalis and pleura pulmonalis are covered with thick plastic exudations to such an extent that absorption is rendered quite impossible, or else the pressure on the lymphatic orifices by the fluid is such that absorption does not take place rapidly. Frequent examples prove to them also, that in multiple instances, when all other measures have been tried and failed to produce good results, a single puncture of the chest-walls has been very efficacious by letting out a portion of the fluid, and thus allowing the hitherto compressed lymphatics to become permeable; and that, shortly after the operatory procedure, whatever fluid remained in the chest had been completely absorbed. And yet these same practitioners will hesitate and fear to perform thoracentesis in an acute attack of pleurisy at the period when the fluid is first produced in any notable quantity.

First, it is affirmed by them that the liquid will surely re-accumulate if withdrawn from the pleura before the morbid process has reached its height.

Second, that the fever will be increased by the puncture, the inflammatory condition heightened, the effusion rendered purulent, and the patient injured in almost every particular by too early appeal to an operation.

In order to sustain the first of these objections, it may be argued that if the vessels are in a similar condition to what existed when the effusion was formed, the fluid will inevitably be reproduced. And of course if we desired to empty the chest each time it refilled, we should be obliged to recur to puncture several times during the inflammatory stage.

Now, if we adopt therapeutic means to diminish the intensity, and to shorten the duration of this process when absorption commences, it indicates that the conditions which gave rise to liquid in the pleura have terminated. Consequently there is little or no probability, unless by imprudence, or the occurrence of some untoward accident, of the reproduction of effusion. To this it may be replied that the above reasoning is faulty, because founded upon an erroneous premise. The re-accumulation of fluid, if drawn off during the formative or ascending period, as it may be termed, is neither necessary nor even probable. First, many cases are already on record where the operation has been performed at this time, and in point of fact the liquid did not re-form. Witness an elaborate and most conclusive article on this subject in the *Mouvement Médical* for 1873 (No. 8, p. 3.), where we find thirty-five cases of simple pleurisy reported. Of these thirty-five cases, twenty-five had been punctured with the aspirator, and six times only the effusion re-formed. Moreover, when the liquid has re-formed, this re-accumulation has usually been partial, or in less quantity than when it was first discovered; and frequently so small indeed was this re-accumulation that the reality of the increase after operation was not established with certainty. Again, in certain cases, when a second puncture has been made, it has been performed *not* to let out an increase of fluid in the chest, but simply that portion of it which remained behind after the first operation. In all the cases referred to the disease has been invariably shortened.

Finally, we would here lay stress on a fact which is occasionally lost sight of, viz., that the use of the aspirator in no way precludes the administration of medicaments, which are indicated by the condition of the

\* Archives Gén. de Médecine, Vols. I. and II., 1872.

patient, previous to thoracentesis. If the patient be robust and of sanguineous temperament, we see no reason why purgatives and diuretics should not be given as useful adjuncts to the operatory procedure. If, on the contrary, our patient is much weakened, and daily losing appetite and flesh, we should, I am convinced, insist most particularly on the exhibition of tonics and moderate quantities of stimulants. Thoracentesis of itself, however, may be considered as being a powerful diuretic, but by a different action from that of *directly* stimulating the kidneys. When a portion of liquid is withdrawn from the pleural cavity of the affected side, the absorbents are by so much relieved from obstruction due to pressure, and can more easily and rapidly exercise their function, and the amount of fluid taken up by them is eliminated finally from the economy by hyper-renal excretion. In one reported case,\* the patient passed as much as two gallons of urine during the twenty-four hours immediately succeeding the operation. This result was manifestly due to operation, as no diuretics, properly speaking, were employed. Moreover, notes have been carefully taken in other cases of acute pleuritic effusion when diuretics were given in large doses, during the continuance of the disease, in order to determine whether or not they produced any appreciable effect on the excretion of urine. According to these observations, no increase or change in the flow of urine could be made out, attributable to the diuretics, but the quantity of urine excreted corresponded almost exactly to the quantity of liquid drunk.†

Again, with respect to the augmentation of the febrile state and increase of the inflammation, this objection is not as yet established; and even though rise of temperature after the operation be admitted, is it clear that the operation itself is the weighty factor in its etiology? Dr. Sydney Ringer,‡ in speaking of a case of thoracentesis which had been under his care, makes the following remarks:

"Even during the fever period, the fluid may be withdrawn by the aspirator without any return of the effusion; nay, the fluid left in the pleura may entirely disappear before the fever declines, and, in cases of this kind (viz., of acute disease), the operation may not affect the fever."

Dr. Sparks§ also reports a case where the temperature was not in the least degree affected by the puncture; it reached the same point (101.8°) on the evening of the operation, as on the evening before and afterwards. Moreover, it has been noted|| that in uncomplicated acute pleurisy there exists a pleuritic fever, of which the mean duration is from twenty-eight to thirty days, without reference to the quantity of the effusion; and although thoracentesis does not notably diminish the duration of the febrile state, made evident by the thermometer, it diminishes considerably the intensity of it. This record does not correspond with that of Laboullène, who found that the temperature, taken immediately after the operation had been performed, was more elevated by two or three tenths of a degree, Centigrade scale, than it was before.

These discrepancies are reconciled, fortunately, if we consider the following important fact, viz., that the temperature, as noted by Laboullène, was taken in the rectum; whereas, in the preceding citation, we have good reason to believe that the temperature was

taken from the mercurial level, when the thermometer bulb was in the axilla.\*

Moreover Laboullène† himself remarks that the axillary temperature is generally lower after than before thoracentesis. This fact may be attributed to uncovering the patient during the time the operatory procedure lasts, whilst the elevation of rectal temperature is no doubt sufficiently explained by the re-establishment of molecular action in the compressed parts of the lung. The *surface* temperature does not remain low, and the day following thoracentesis it is again equal to what it was prior to the operation. This circumstance seems to justify the interpretation of it which has been assigned. I would here call attention to the temperature of the affected side.

Some authors have maintained that it is more elevated than on the sound side; according to others, this belief is incorrect.‡

In favor of the former statement, Jobé Duval§ has not only found the temperature of the affected side before thoracentesis always more elevated than the healthy one, but has also observed that the difference is augmented after the operation. He attributes this result to thoracentesis, and hence argues, in cases of pleuritis with effusion and when fever is present, it is preferable to abstain from puncture of the chest-walls. In my opinion, this conclusion is not fully established: First, because Jobé Duval does not show whether the "augmented difference" of the temperature is due to increase on the affected side or diminution on the healthy one after the operation. Moreover, whilst Laboullène has noticed an increased rectal temperature after the operation, he does not speak of the *surface* temperature, at this time, of the affected side. Now, as there is a general increase of temperature throughout the body after thoracentesis, owing to "the re-establishment of molecular action in the compressed parts of the lung," so there may be, and is probably, greater increase of temperature on the affected side, as the one where the unembarrassed lung is better able to fulfil its functions, and the interchange of chemical elements which takes place in its alveoli is permitted to do so untrammelled by a great load from external pressure. Analogy, with other morbid conditions, will seemingly justify my explanation. In erysipelas we have a general elevation of temperature, and a still more increased local one over the affected regions of skin. In paralysis of certain muscles, or an entire limb by compression of the animating nerves, we have, on the contrary, local reduction of temperature. Take away the pressure, and local temperature rises.

Let us apply this knowledge to our cases of acute pleurisy. As in erysipelas, we have an acute febrile disease, but with a temperature elevated even more locally than generally. Take away the pressure of the effusion, which makes the *difference* between the local and general temperature somewhat less than it would be without it, and the local temperature on the surface of the diseased side rises. And it is evidently no more essential to the truth of this explanation that the skin over the thorax be inflamed, than it is for the skin over a deep-seated abscess to be heated otherwise than by the inflammatory processes going on in the soft tissues underneath. Whatever may be thought of these theories, one fact remains acquired and incontestible, namely, that thoracentesis prae-

tised during the febrile period of pleurisy has no injurious effect upon the ulterior march of the effusion. It would therefore seem, without having regard to the slight variations of temperature after the operations, that there is every advantage to be gained by not deferring it until the fever has diminished or disappeared. The liquid accumulated in the pleura, according to Dieulafoy, can only have a bad influence; it plays the rôle of a foreign body; it interferes with the function of the lung, and narrows the field of hematosis. We have, therefore, good reasons for ridding the patient of it.\* Again, if the increase of temperature were due to the operation, the pleura costalis ought to give some local evidence of increased inflammatory change due to the puncture. Now, positive proof is afforded by post-mortem examinations, made shortly after the use of the aspirator, in which "the place where the chest had been punctured was difficult to discover, and was not surrounded by any areola of inflammation." This objection, moreover, that thoracentesis is a fresh cause of inflammation of the pleura, is of somewhat ancient date, and has not lacked complete refutation. By reference to numerous clinical histories of this operation, to experiments made on animals, and to recorded wounds of the chest in man, Trousseau has shown the innocuousness of a puncture of the chest walls with a pointed instrument.

No matter how many punctures may be made as an experiment, on sacrificing the subject, "nothing further has ever been found than a little blood at the place of the wounds, and traces of slight inflammation."<sup>†</sup>

Moreover, in wounds of the chest in man with a pointed or cutting instrument, their gravity depends altogether upon the complications which accompany them, and except for these complications wounds of the chest are exempt from dangers. From an impartial survey, therefore, of the two principal objections urged latterly against thoracentesis, during the acute febrile stage of the disease, I derive the conviction that they are without importance, inasmuch as they are based upon incorrect premises.

With respect to the fear of transforming a serous or sero-fibrinous effusion into a purulent one by the use of the aspirator, this objection is without weight. Dieulafoy has never seen it once among several hundred cases in which he has operated by puncture, and regards it to be a coincidence rather than the consequence of the operation. No doubt, if air were permitted to enter the pleural cavity, purulence might readily follow, as it did occasionally with the ancient manner of puncture by an ordinary trocar, after the method of Reybard. And, even under these circumstances, purulence of fluid after the operation was much less frequent than is usually believed.

In twenty-eight cases tabulated by Dr. G. H. Evans,<sup>‡</sup> the operation was performed more than once; in twenty-four of these the fluid drawn off was serum each time; in the remaining four cases it was purulent in one or more of the subsequent tapplings. Besides, we should never lose sight of the following fact, viz., that a serous pleuritic effusion has of itself, in certain constitutions, a tendency to become purulent, and without any complication, occasioned either by intercurrent disease or an operation, will naturally and inevitably take on this change. With children this is especially true. For in them simple, non-secondary

pleurisy transforms itself with an extreme rapidity and facility into one of purulent nature.\*

Whenever, therefore, in children absorption of effusion is delayed, we shall have to anticipate this probable modification in the nature of the liquid. This is so exact, that it has been said by high authorities a chronic case of simple *serous* pleurisy does not exist among children. In more than thirteen thousand patients of all kinds, which have been cared for during eleven years, in the wards of M. Barthez, of Paris, not a single instance of it was noted. And Barthez himself affirms that he has never, in his very extensive experience with children, seen a case of this nature.† In basing our judgment on one of the facts which may be encountered as a tolerably frequent sequence of thoracentesis, we should carefully consider attendant conditions, so as not to have ourselves biased against the operation, and to attribute to it what in reality is a mere coincidence, and without relation of an effect to a cause.

## PHOSPHORUS ASSIMILATION.

THE ELEMENT AND ITS COMPOUNDS, CONSIDERED AS TO AVAILABILITY.

By R. W. GARDNER.

JERSEY CITY, N. J.

WHEN phosphorus is administered in a free state, its irritant action forms the greatest objection to its use, and limits the quantity which may be given with safety; it is also necessary to give it upon a full stomach, as a precautionary measure, as otherwise it is found to attack mucous surfaces, and produce irritation; the extent of such action depending upon the quantity administered, or the length of time the remedy has been continued. The largest dose usually given is about one-twentieth of a grain, though one-twelfth has been administered, but not until the tolerating power of the patient had been carefully tested. Given in doses of from one-hundredth to one-thirtieth grain, it often produces dyspeptic symptoms, and the remedy has to be discontinued.

Let us consider why this occurs. Phosphorus has such a powerful affinity for oxygen, that it must be kept under water, for when exposed to atmospheric air its union with oxygen is so violent that it inflames spontaneously. This explains its corrosive action in the stomach, modified, no doubt, by its surroundings, but nevertheless capable of producing the most serious results upon the delicate mucous surfaces which are directly exposed to its influence.

Phosphorus cannot be absorbed in its pure state; a certain degree of oxidation must have taken place before it reaches a condition adapted for assimilation.

What this degree is, has not been definitely determined; it is certainly not more than one atom of oxygen, and possibly less.

When it has thus become partially oxidized, however, it has lost its corrosive action, and is then, and not until then, in a condition to fulfil its valuable agency in contributing to nerve-power and vital force. The remedial action of phosphorus is doubtless exerted from the time it has become sufficiently oxidized for absorption, and during the whole of its subsequent oxidation, until it has finally reached its ultimate oxidized state, the phosphate.

\* *Voyet, De quelques Observations de Thoracentese chez les Enfants*, Thèse, Paris, 1870, p. 16.

† *Dr. Verhae, Thèse de Paris*, 1865.

My reasons for forming this conclusion are, that the eliminations of phosphorus from the body are *always in the condition of phosphate*, and also that the phosphite is so firm in its chemical behavior as to lead naturally to the belief that for this purpose it is unavailable, or to use a vulgarism, it has "burned out," and having passed its period of usefulness, is eliminated.

Phosphorus exists in the vegetable world in the condition of phosphate only; in animal tissue and in fish, etc., in a partially oxidized state, constantly undergoing the oxidizing process, and finally being thrown off as effete matter.

Do not this at least partly explain the superior vitality and nervous power of those who partake largely of animal food?

It is also rarely the case that animal organisms appropriate elementary substances directly. If we examine the matter, we will find that all articles of food contain these elements in a condition of chemical combination, and by a reciprocal action nature discards useless or exhausted substances for such as she requires, each immediately forming new compounds, the one destined for elimination, the other for assimilation.

These views naturally lead to the conclusion that phosphorus should preferably be administered in its lowest oxidized state rather than in the elementary condition, and never, where its assimilation is desired, in the condition of phosphate.

The next question is, how to get at it? Phosphorus, uncombined, passes directly to its highest condition of oxidation, unless retarded by chemical union with a base; this leads us to a second conclusion, viz :

That phosphorus in its most desirable form cannot be obtained except by such a chemical combination as will stay the oxidation at this point, and render it available for therapeutic action. In the search for such a compound, there seems none so well suited to the purpose as the several hypophosphites. They embrace quite a range of salts. Lime, soda, iron, potassa, manganese, pinnia, etc., each capable of playing an important part in a subordinate capacity, while the phosphorus element becomes the most important. The phosphide of zinc has been suggested and used to some extent, but this does not seem a sufficiently definite compound, producing irritant action and unpleasant results. The hypophosphites, however, while entirely non-irritant, and held by such a feeble affinity as to be readily decomposed in the stomach, not only contain oxygen in its least combinable proportion, but represent a larger proportion of phosphorus, relatively, than any of its other compounds. It is found, however, that unfortunately their therapeutic value is much lessened by the impurities always found in the commercial salts, and the ordinary preparations of them. It is very desirable that they be administered in a perfectly pure and neutral state, and unless they have been given in this condition, their medicinal value has not been properly tested. This is proven by the superior results attained by the use of such salts at the European hospitals.

The salts should be converted into solutions, the impurities removed by proper chemical means, and such solutions preserved against putrefaction and atmospheric influence by conversion into syrups. Sugar is the best preservative agent, as it does not cause decomposition, and excludes atmospheric air. Prepared in this manner, the salts have been found much more prompt and assimilable. They should be almost wholly devoid of medicinal taste, except in the case

of iron, and in this, the ferruginous taste is only mildly perceptible. The syrups of lime, of soda, and of potassa should be entirely free from the alkaline taste common to these preparations, and should never let fall a precipitate, which is a sign of the presence of impurity.

## Progress of Medical Science.

ECTROPION TREATED BY TRANSPLANTATION OF A LARGE FLAP WITHOUT A PEDICLE.—Dr. Wadsworth, of Boston, reports the following case on which he operated successfully by the above method, recently proposed and carried out by Mr. Wolfe, of Glasgow. The case seems to be one that merits careful attention, as it points in the direction of decided improvements in our means of dealing with deformities, especially such as often result from cicatricial contraction following injuries. A healthy girl of sixteen was extensively burned about the face in infancy. As a result of the contractions of the cicatricial tissue, the left upper lid was shortened, the eyebrow and lower lid much pulled downwards, and the conjunctiva greatly everted. On attempting to close the lids there was a broad space between the puncta-lachrymalia. The operation consisted in making an incision through the skin of the lower lid, about one and a half lines below the lashes and parallel to them, the wound extending from just below the punctum to a point half an inch beyond the outer canthus. The tissues were then dissected until the edges of the lower lid could be brought into apposition with the edges of the upper lid, when the two lids were sewed together. The raw surface thus left measured  $1\frac{1}{2}$  inches in the horizontal direction and  $\frac{1}{2}$  of an inch in the vertical. A piece of skin from the inner side of the forearm  $2\frac{1}{2} \times 1\frac{1}{4}$  inches in dimensions was then dissected up, stripped of its subcutaneous connective tissue, and implanted in the wound, where it was detained by two delicate sutures. Gold-beater's skin was then laid over the lids and covered by thick layers of cotton wool secured by a flannel bandage. The sound eye was also bandaged to secure immobility. The dressing was not disturbed for forty-eight hours, when the bandage and cotton wool were removed. It was then found that the outer two-thirds of the graft appeared to have united without swelling, while the inner third was somewhat uneven, for the inner two of the sutures intended to hold the lids together, having cut through the lower lid, had fallen, so that mucus and tears had run out from the conjunctival sac and smeared this portion of the graft and the skin about it. A part of the gold-beater's skin was then cut away and the skin cleansed with a carbolic-acid solution. A little cotton moistened with carbolic-acid lotion was then laid over the inner canthus, and the packing and bandage renewed. On the next day the graft was in good condition throughout. The gold-beater's skin was removed on the fifth day; on the eighth the bandage was omitted and the sutures holding the lids together were removed. The graft was then firmly united. About the fifteenth day the horny layer of the epidermis was thrown off from the whole surface. Dr. W. observes that the shrinkage in these cases is decidedly greater than when a pedicle is left. Its dimensions, after four months, were  $1\frac{1}{2} \times \frac{1}{2}$  inches as compared with  $2\frac{1}{2} \times 1\frac{1}{4}$  inches at the time of the operation. In this case the size of the graft was greater than in

either of Wolfe's cases, but it is thought that if a larger surface is to be covered it will probably be better to employ two or more grafts, because the difficulty in making them lie flat increases with the size.—*Boston Medical and Surgical Journal*, December 28, 1876.

**EXCISION OF THE ELBOW, WITH ITS FINAL RESULTS.**—Dr. Beach, of Boston, has collected and reviewed a series of twenty-one cases of this operation, all of which occurred in the hospital service of Dr. R. M. Hodges, within the last ten years. The results, which he gives, are attributed to the observance of certain rules in carrying out the operation. In the first place, the single straight incision is made downwardly over the olecranon, so that the tissues are not cut across, allowing also "the connection of the triceps extensor tendon, with the investing aponeurosis of the arm and forearm to be preserved almost intact." An attachment for the muscle is thus retained which diminishes to a certain extent the loss of power following its unavoidable separation from the olecranon." In the second place he lays stress upon the fact that it is essential to regard the attachment of the brachialis anticus, for though, he observes, this muscle is commonly stated to be inserted into the coronoid process of the ulna, excision on the dead subject shows that the attachment is into the shaft of the ulna also. This being the case, it is usually possible to slip in the saw, always from the inner side of the arm, between the base of the process and the shaft, thus leaving the muscle firm in its connection; the attachment of the biceps should also be respected, for Dr. H. believes that it is rarely necessary to remove any part of the radius below the bicipital tuberosity. In deciding as to the sacrifice of bone, it should be at the expense of the humerus. Regret may sometimes be felt at not having excised enough, but seldom at having removed too much.

Dr. Bigelow's plan was suggested since these operations were done. The incision is similar, but in removing the articular surface he preserves the internal and external condyles of the humerus, thus affording better chances for good pronation, supination, flexion and extension by saving the point of attachment of those muscles that originate from the condyles. In fourteen of Dr. Hodges' cases the excision was for injury; of these five died. In four the operation was for disease; all recovered and had useful arms. Three cases were of deformity; two recovered and had useful arms, and one died. The author, in conclusion, states that "in twenty-one cases where amputation must otherwise have been performed, this report exhibits fifteen arms preserved, several of them being useful to a remarkable degree, and all of them, except one, retaining motion of the elbow, forearm, hand, and fingers." During the forty years that the operation has been practised in the United States, Dr. H. doubts whether its full range of usefulness has been reached.—*Boston Med. and Surg. Journal*, January 4, 1877.

**THE ALIMENTATION OF INFANTS.**—M. Magne, having been struck by certain results obtained in the alimentation of animals, recently read a long memoir before the *Académie de Médecine*, in which he developed the idea that the same principles should be applicable to man, and that consequently, instead of rejecting all other aliments than milk during the first months of infancy, we should habitually have recourse to them, and recommend them. This doctrine, borrowed from veterinary surgery, met with decided opposition from all sides. M. Bouley called attention to the great differences that exist between the herbi-

vora and the carnivora, the former being very precocious and able at an early period to live an independent life, while the latter remain for a long time incapable of seeing and walking, and unable to procure any other nourishment than the mother's milk. M. Depaul argued that premature alimentation could only result in augmenting the mortality of infants, and would greatly increase the number of cases of rickets. M. Devilliers said that observation has proved that the mortality is least in those countries in which the practice of suckling the infants is most common, and is prolonged during the first periods of dentition. This is not a reason for rejecting the employment of solid food at all times, but it should only be resorted to towards the end of the first year, and after the capacity of the infant to sustain the new mode of alimentation had been carefully ascertained.

M. Guérin took substantially the same view as the previous speakers, but added that he had often observed that infants who had been fed on the mother's milk alone for twelve or fifteen months became very lymphatic. They suffered in consequence of a too long continuance of the same régime. While rejecting, however, premature alimentation, he insisted strongly on the value and safety, in appropriate cases, of artificial nourishment with the milk of animals. One woman in Besançon brought up successfully on the bottle ninety-six children. M. Guérin recommends good cow's milk, to which a little sugar and a variable quantity of water should be added.

M. Devergie referred to the difficulty occasionally experienced of finding a nurse whose milk agrees with the child. He has found that little reliance can be placed on the signs that are usually said to indicate the good or bad qualities of a nurse, and thinks that microscopic examination affords the most reliable information as to the quality of the milk. He has examined in this way the milk of 172 nurses, and distinguishes three varieties of milk, viz.: *strong milk*, in which the globules are large and well defined; *medium milk*, which contains a mixture of large, medium-sized and small globules; *weak milk*, which contains only very small globules. The number of the globules is also an indication of the poverty or richness of the milk. Examinations of the milk of different cows give similar results. When one breast is not used, the milk it contains becomes very thick and creamy, consisting of a mass of globules without appreciable serum, under the microscope. M. Devergie derives from these facts the following rules of practice: 1. When the mother has never nursed her child, choose a nurse with *medium milk*, which is most apt to agree with the child. 2. When the mother has nourished the child for some time examine her milk microscopically, and choose a nurse whose milk presents analogous characters. 3. When the milk of one nurse disagrees with a child take another nurse whose milk presents the opposite microscopical characters.—*Journal de Méd. et de Chir.*, November, 1876. *Gazette Médicale de Paris*, November 11, 1876.

**EXTIRPATION OF THE KIDNEY.**—Dr. Dabney has collected twelve cases in which this operation has been performed, the operators being Peaslee, Simon (2 cases), Schitelig, Von Bruns, Gilmore, Meadows, Durham, Peters, Brandt, Stoddard, Campbell. The patients recovered in four of the cases.—*Amer. Med. Weekly*, December 23, 1876.

**PHOSPHATE OF LIME IN THE TREATMENT OF FRACTURES AND WOUNDS.**—Clinical observation has already confirmed the value of this drug, but a special phenomenon, which in a certain number of cases gives evi-

dence of the activity of the reparative process going on in the injured bones, has apparently, as yet, escaped observation. Several patients in the wards of M. Dolbeau, in Beaujon, to whom this drug was administered in doses of thirty grains three times a day, complained of a sensation of tingling in the affected limb, which ceased when the drug was withheld and reappeared when its use was resumed. The following cases exemplify this fact:

1. Alexandrine S.— entered the hospital on July 13, 1867, with a comminuted fracture of the left humerus, complicated with a small external wound. Several methods of treatment were tried, but on the 8th of May, 1868, the fracture was still ununited. A spoonful of the syrup of the lactophosphate of lime, representing fifteen grains of the salt, was then given three times a day with the meals; at the end of eight days the dose was doubled. During the first week the patient's appetite became excessive, and it continued so for three weeks, after which it returned to its normal condition. After the fifth day of the treatment the patient felt stronger, and she complained of a sensation of tingling, and of continuous pricking in the legs and arms, especially at the seat of fracture. The phosphate of lime was continued in the same large doses, and caused no disturbances of the general health. The formation gradually decreased in severity after the first week. The limb was placed in a silica splint, and when this was removed, on July 8th, the consolidation was almost complete.

2. Charles D.— received a compound fracture of both bones of the right leg on May 1st. On June 1st the wound had healed, but the callus was still soft. On June 3d he was ordered two spoonfuls of the syrup of the lacto-phosphate of lime three times a day. After twenty-four hours his appetite began to increase, and it became excessive about the eighth day. At the same time he complained of a marked sensation in the affected leg, which he compared to that produced by electricity and by numerous prickings. On June 20th the callus was resistant, although mobility still existed.

3. X.—, fracture of humerus on June 12th. Consolidation well advanced on July 9th. On the 17th a spoonful of the syrup was ordered three times a day; these doses were doubled on the 19th. On the 22d the appetite was excessive, and the patient felt in the fractured limb some formication, which gradually became more marked. The drug was withheld for four days, and on the fourth day all the phenomena had disappeared. It was then resumed in the same doses, and after three days the patient complained anew of formication.—*La Tribune Médicale*, December 3, 1876.

NOTES OF A CASE OF PHLEGMONOUS GLOSSITIS.—In view of the comparative rarity of idiopathic inflammations of the tongue, the following case reported by D. Fienzal may be of interest to our readers, as it illustrates both the excessive gravity of glossitis and the incontestable value of surgical interference:

M. P.—, law student, aged 28 years, was seized on a Sunday, without appreciable cause, with pain at the base of the tongue, accompanied by tension and difficulty of moving the organ; the teeth were good, and there was no ulceration of the tongue; an initial chill, followed by high fever, nausea, and extreme pain manifested themselves during the first day; on Monday the mouth was opened with some difficulty; and on Thursday the tongue filled the entire buccal cavity from the floor to the roof, and extended beyond the dental arches, which painfully compressed its

tissue. The difficulty of swallowing was extreme, the saliva was constantly dribbling out, and the interference with respiration demanded prompt intervention. A bistoury was with difficulty introduced into the mouth, with its flat surface parallel to the tongue, turned and plunged into this organ as far back as possible, making an incision  $1\frac{1}{2}$  inch long, and at least  $\frac{1}{2}$  inch deep. A similar incision was made on the other side of the tongue. The hemorrhage was abundant, and relieved the patient a good deal. On the next day an obscure sensation of fluctuation was perceived on passing the finger over the back of the tongue, and on the same evening the symptoms again became severe. On Sunday, the tongue hung out of the mouth; it was seized in a handkerchief and a bistoury plunged deeply into its substance in a sloping direction. The hemorrhage was free but no pus came. The bistoury was, however, introduced a fourth time nearer the middle of the organ, and a stream of phlegmonous pus, mixed with blackish blood issued forth. The patient felt relieved at once, and in a few moments was able to swallow, to breathe easily and to speak. The tongue soon regained its normal volume.

Dr. Fienzal had great difficulty in discovering an adequate cause to account for the rapid development of such dangerous symptoms. The usual causes of glossitis mentioned in the text-books seemed to him utterly insufficient. He finally discovered that on the eve of the day on which he was taken ill, the patient had indulged for a long time in certain voluptuous practices in which the organ of taste played a disgusting and unnatural role.—*Gazette Médicale de Paris*, December 2, 1876.

TEMPORARY GLYCOSURIA DURING LACTATION.—The following are the conclusions of a paper on this subject, communicated to the *Société de Biologie*, by M. A. Gubler:

1. Glycosuria is not a normal phenomenon of the state of lactation.

2. It is met with after the suspension or premature suppression of nursing, provided the nurse be in good health, or at least be not suffering from any serious disturbance of the important functions of life.

3. In other words, glycosuria only appears as a consequence of a disturbance of the equilibrium between production and consumption, which causes a lactosemia, comparable to the superalbuminosis of the blood, which leads to dyscrasia albuminuria.

A transitory albuminuria does not accompany the glycosuria under these circumstances, partly because albumen, being a colloid substance, passes through an animal membrane much less readily than sugar, which is a crystalloid substance; partly because albuminuria presupposes at least a renal hyperæmia, while glycosuria is produced without any anatomical modification of the gland; finally because the quantity of albuminoid matters taken back into the blood in the resorption of the milk, is small compared with the amount of sugar of milk.—*Gazette Médicale de Paris*, November 25, 1876.

AN EXPENSIVE MEDICINE.—A homœopathic pharmacy advertises "Lachesis, 3d Centesimal Trituration, one dollar (\$1.00) per ounce." As their other triturations are worth but twenty-five cents an ounce, we presume the difference depends upon the value of the medical ingredient. As it is in the proportion of one part in a million, an ounce of the pure drug would cost seven hundred and fifty thousand dollars.

## FRAUDS IN LIFE INSURANCE.

THE recent developments of fraud in life insurance have opened the eyes of the public concerning the manner in which the affairs of some of the companies are managed. It can hardly be considered a comforting assurance to policy-holders that the practice of making false entries, quoting and swearing to fictitious values, are quite common on the part of directors of these enterprises; and yet such is asserted as a fact by a director of one of the companies whose villainies have been recently unearthed. Indeed, we fear that, as the investigations of the Superintendent of Insurance proceed, there will be more shaking among the dry bones of sepulchred honesty than was at first anticipated. With the strictly business management of such companies we do not at present care to refer, except in the way of stimulating greater caution on behalf of prospective policy-holders in the selection of well-established and well-managed companies. But this is by the bye.

An item in the report of the Deputy Insurance Inspector regarding the excessive mortality of an insolvent company brings up for discussion a subject which is more especially interesting to the profession. As a general question of principle, which may affect the prosperity of any company, its significance cannot be and must not be ignored. Although the text for our remarks may be taken from the report before us, we trust that we may be understood as speaking with impartiality, and with no desire of reflecting upon the capabilities of the medical examiners connected with this particular company. We wish merely to say a few plain words in a general way upon the great importance of medical examination in life insurance, for which the statements in the report give us such a direct invitation. The Deputy Superintendent of Insurance, in estimating some of the reasons for the failure of the company, very pertinently says:

"I find also that the mortality of the company was excessive; and to conceal the fact, large amounts expended for death-losses were carried annually into expenses as 'paid for forfeited policies.'"

In searching for the reason of this excessive mortality we naturally direct our inquiries toward the management of the medical department. No one doubts that to the latter belongs all the responsibility of increased death-rates; but whether or not it is allowed to assume it and govern its actions accordingly, is a matter with which, as a profession, we have a great concern. From what we know of the medical gentlemen connected with the insurance company in question, we are not willing to believe that they have been derelict in their duties as examiners. Thoroughly competent to exercise such functions as belong to that office, we are able to explain the increased death-rate in no other way than by the suspicion that their advice was in many cases ignored, and their recommendations overridden by superior authority. Assuming the latter to be the most plausible explanation for the particular losses sustained, we are brought face to face with the old question concerning the relations of medical examiners to life insurance companies. We have always held that the office of medical director to an insurance company was one of the greatest importance. It is impossible to underrate it even in comparison with that of Actuary, General Agent, or President. As the prosperity of the company must depend upon the safety of the risks, the value of a professional decision regarding them must rank proportionably high. The responsibilities involved in such decisions are as weighty as those which govern the investment of the funds in real estate or in stocks. And yet we find that the position of medical director is, as a rule, a very subordinate one. Generally he is a mere figure-head to quiet the suspicions of policy-holders and give the appearance of honesty of intention on the part of the stockholders. In many instances the medical examination of an applicant for life insurance is so much a matter of form—so much a matter of what is judged by the higher authorities as one of pecuniary policy—that a certificate of actual unsoundness is entirely ignored, and a policy granted accordingly. Under such circumstances the medical officer is made professionally accountable for what he evidently has little or no power to control.

The very fact of his occupying the position of medical director or medical examiner presupposes his fitness for the discharge of his duties, and should give his professional decisions the respectful courtesy of unquestioned authority. But every one knows that the rule which should obtain under the circumstances is exceptional rather than general.

While we must admit that the taking of improper risks may be thus explained when the companies have competent and conscientious examiners, we must not lose sight of the possibility of an equally reason-

able explanation, from the fact that the examinations are often trusted to unqualified persons. In either case the companies are to blame. It is no excuse to say that properly educated men cannot always be obtained for these offices. Too often medical appointments are made more for pecuniary and social considerations than for professional qualifications. So well is this understood, that an appointment is always supposed to imply some close friendship with the president or one of the board of directors. It would be absurd to believe that such a system is not liable to gross abuse.

Again, in reference to possible professional incompetency it is fair to offer the explanation that, with few exceptions, the salaries paid for medical examiners are not sufficient to secure first-class talent and accomplishments. Not many days since the president of a prominent life insurance company, in order to explain why he should receive a large salary, gave as the reason the great responsibilities of his office. If the latter excuse could apply to the medical directors and examiners of the different life insurance companies throughout the land, there would be no complaint concerning the amount of the salaries paid for valuable professional services.

It is not our purpose to treat of the general question of relations of medical examiners to life insurance companies in all its details, but simply to place the responsibility of an excessively high mortality in any given company where it rightly belongs. The whole matter sums itself in this: if the medical directors and examiners are competent and conscientious men, their decisions regarding the character of a risk should be authoritative and final. If then any mistake is made, the burden of an explanation should rest with the one who is legitimately vested with the responsibility. If these explanations are not satisfactory, a change is easily made. If the salary is not sufficient to tempt the proper men to take the place, it should be made so.

Considering the ease with which these reforms can be made by any insurance company, there is as little excuse for a high death-rate as for the peculiar methods of concealing the facts of other frauds by false balance-sheets, by the transfer of fictitious stocks, or the inflation of the value of real estate.

#### MUNICIPAL LUNATIC ASYLUMS.

OCCASIONALLY the details of some reported outrage come to us from some one of the municipal asylums, and for weeks the daily prints indulge in violent attacks upon asylum management. Such onslaughts, we are well aware, are rarely characterized by any spirit of fairness, but, on the contrary, are too unjust and abusive to have much weight with the intelligent portion of the community. But is there not sometimes a little flame where there is so much smoke? Even though the complaints of the patients are exaggerated

and based generally upon fancied wrongs, are they not sometimes well-founded reasons for investigation and reform? We think so. Strait-jacket muff and rough attendants, provoke these stories of personal suffering, and are bad enough in themselves; but beyond these, there are greater evils which flourish particularly in the asylums of large cities, and very little has been said about them. We allude to overcrowding, insufficient and poor food, and incompetent medical attendance.

Dr. Bucknill, who wrote of our city asylums, spoke of them as being "under the vulgar rule of a municipality moved only by motives of party politics and unintelligent economy." Now while this statement is true in some respects, it is unfair in others. There are some medical superintendents of asylums who have so little ambition to improve the institution committed to their care, that their asylums become little more than almshouses, where insane paupers are huddled together, and where intelligent medical treatment and advantages for scientific research are neglected. This is the penalty of placing incompetent individuals at the head of asylums, instead of paying salaries that will command medical men of brains and ability.

This condition of affairs does not exist, however, in all the municipal institutions; some men take so much interest in their duties, that they have brought their institutions to a high state of perfection. This is the case with Dr. MacDonald's asylum on Ward's Island, which was especially praised by Bucknill.

Too much attention is paid to the whiteness of the floors, and too little to the physical treatment of the patients. The insane are left to the care of ignorant attendants, or the whole medical direction devolves upon two or three young physicians, as is the case in one asylum in New York where there are thirteen hundred patients. The food is simply atrocious: meat which is two-thirds bone and gristle, black bread, and questionable potatoes. That the medical superintendent is often aware of this state of affairs there is no room for doubt.

#### HOMEOPATHIC MEMBERS OF STATE EXAMINING BOARDS.

THE Medical Society of the County of Travis, Texas, is much exercised over the prospective appointment of an homœopath as a member of one of the Medical Examining Boards of the State, and have published a long and earnest protest against it. It appears that one of the District Judges, who has the power to make such appointments, has signified his intention of having at least one representative homœopath as a member of the Board. As regards his right so to do, there can hardly be a question, since the law regulating the practice of medicine in that State merely requires an examination of candidates "in the elemen-

ry branches of medicine, anatomy, physiology, chemistry, surgery, and obstetrics, which are understood like by all schools, and does not require examination in those branches involving difference of opinion." The claim of the Medical Society is, in substance, that a competent Examining Board cannot be secured with an *irregular* upon it. This is, however, so clearly, in the eyes of the law at least, a matter of opinion that it cannot be accepted with the force of a fact. If the *regular* is acknowledged to be competent to examine in the prescribed branches, not the most liberal interpretation of the purposes of the law can prevent his appointment to any office in which the mere exercise of such functions is required. We sympathize with the Society in their laudable efforts to contend against quackery, but in the present instance we can see no help for them. It is, after all, another illustration of the inutility of legislation in matters purely medical.

#### UNHEALTHY HOSPITALS.

THE death of four female inmates of the Epileptic Hospital on Blackwell's Island, supposed to be due to malarial influences, resulted in a sanitary survey of the building. Dr. McLane Hamilton, one of the visiting physicians to the institution, in recommending the immediate removal of the hospital, made the significant statement that a large number of the patients were more or less affected with malarial poisoning. On inquiry regarding the cause of this state of things, it was discovered that the outbreak of the epidemic was due to the condition of the ground on which the hospital stands. That there is good reason for this assertion, appears from the fact that this particular portion of the island was formerly marshy ground, which had been filled in from garbage and sweepings from the city. The removal of the patients has been repeatedly urged during the past few years; and now that such a recommendation is associated with some deaths, which have caused a public sensation, it should be acted upon.

If the present experiences of the Board of Commissioners shall be fraught with any good in the prevention of future evils in hospital construction, it will be well. With the system, however, of entrusting contracts to persons ignorant of the first principles of sanitary requirements, of allowing the construction of large public buildings upon pestilential soil, there does not seem to be much hope of reform. Indeed, how can we expect it to be otherwise when one of the largest hospitals of our city, governed by one of the most intelligent and influential boards in the country, has been built upon the edge of what was once a swamp, and in defiance of the best-established principles of hospital construction? In regard to the Epileptic Hospital, the only proper means of preventing the spread of an epidemic should be taken at once; but it is easy to see that, before this can be done,

the Commissioners will be called upon to prove the relative value of the factors, prevention and cure.

#### PREVENTION OF SCARLET FEVER.

THE circular recently issued by the Boston Board of Health, and published in another column, may be considered in many respects as a model one. As such we commend it to the attention of the health authorities of this and other cities. Considering the contagiousness of this disease, and its great fatality, there is no middle ground to be taken regarding measures to prevent its spread. Not long since we referred to the danger of disseminating the poison by funerals, and the steps which had been taken to prevent such an occurrence in our own city; but this is only one of the many means to be adapted to the end. The promiscuous intercourse of members of a family, in which scarlet-fever exists, with outsiders, either by direct contact or through the media of clothing and the like, is one of the most prolific causes of spreading the disease. It may not be irrelevant to the discussion of such possibilities, to say, in this connection, that some physicians are not as careful as they might be while in attendance upon such cases. Numerous melancholy examples of such neglect are on record, of the disease being carried from one family to another. When we take into account the fact that it is only with the utmost care, on the part of physicians and attendants, that the spread of this dreadful disease can be arrested, we cannot laud too highly every new effort made in the proper direction. The duty of the physician in attendance upon scarlet-fever patients is so obvious, in regard to the enforcement of the strictest quarantine, that it is unnecessary to urge his attention to every possible detail. The protection of the school children in Boston, by the recent orders of the Board, is calculated to meet a requirement which has been felt in every city where large schools abound. We are not aware that any similar provision has been made in our own city; at least the lack of power, or the want of disposition to enforce it, is quite apparent in the number of cases which owe their origin to direct association in the school-room. Pursuing this part of the subject further may tempt us to reiterate some of the arguments in favor of medical inspection of schools, and cause us to stray from the direct purpose of these remarks.

#### OUR WATER SUPPLY.

THE question of water supply for our city is still under discussion by the Board of Aldermen. The opinion is entertained, and we think with good reason, that the present water-shed of the Croton River, and the new aqueduct in course of construction, are sufficient to supply the wants of the city for a long time to come. While it is acknowledged by the Water Commissioners that there is a great waste of water in different parts

of the city, and notably in the tenement-house districts, the use of water meters is not advocated. The objection to the measure, more especially urged by His Honor the Mayor, that for strictly sanitary reasons there should be no restriction of water privileges, reasonable as it may appear, does not meet the question at issue. While it is quite necessary that water should be freely used, it is equally necessary to prevent actual waste. How these apparently conflicting conditions can be best reconciled to the interests of the people at large, is still somewhat of a problem.

Thus far, however, the system of preventing waste of water which is adopted by the authorities of Liverpool gives the best promise of satisfaction. In that city an instrument is used to indicate the velocity of the flow of water through the pipes, and when this velocity is unduly increased a waste is at once detected and traced to a particular dwelling.

## Reports of Societies.

### NEW YORK PATHOLOGICAL SOCIETY.

*Stated Meeting, Dec. 27, 1876.*

DR. CHARLES K. BRIDGON, PRESIDENT, IN THE CHAIR.

DR. HEITZMANN reported the case of false membrane in the joint, presented by Dr. Sayre, to be real cartilage.

#### POPLITEAL ANEURISM—INTERESTING QUESTIONS IN DIAGNOSIS.

DR. MASON presented a specimen of popliteal aneurism, taken from an inmate of the Colored Home, a man aged 64 years, who came under observation in May last. The patient had syphilis eight years before, and afterwards suffered from its secondary manifestations. In October, 1875, while jumping over a ditch he fell, and at the same time something gave way in the back of the left knee-joint. During the following February the swelling became very painful, and was accompanied with a beating sensation of the posterior portion of the knee. When he entered the hospital no pulsations could be felt either in the anterior or posterior tibial arteries, and the limb was much swollen and œdematous. Dr. Mason ligated the femoral on the 15th of May last, in Scarpa's space. The patient did well until the 4th of June, when blebs appeared upon the dorsum of the foot in the vicinity of the toes, and gangrene followed. The line of demarcation formed in the course of ten days, and on the 22d of June, Dr. Lyon, the house-surgeon, removed the limb through the middle of the femur. The patient did well for eight days, when he sank from exhaustion, induced by the extreme heat prevailing at the time. The aneurism sprang from the anterior surface of the artery, and the tumor was nearly consolidated. The wound of the artery healed up nicely.

DR. MASON presented a second specimen which had been removed from a young German, aged 24 years, who had entered Roosevelt Hospital, March 18, 1876. Five months before, he began to suffer with pain in the posterior portion of the left knee, particularly

after a hard day's work. He could give no history of the injury, but stated that for some time past having been engaged in putting down carpets, he thought that he might have "strained the joint." He was seen outside by several physicians, and the disease by some was regarded as rheumatism, by others a incipient hip disease. On admission to the hospital while examining the joint, Dr. Mason observed an oval tumor situated in the left popliteal space, measuring 2½ inches vertically, and two inches transversely. It pulsated strongly, the pulsations being eccentric and plainly seen by casual inspection. There was beside a loud and distinct bruit. On compressing the femoral artery in the groin, the pulsation instantly ceased, and the tumor diminished in size. The pulsations of the anterior and posterior tibial arteries were very much diminished. The knee-affected limb was warmer than the opposite one, while the leg below was cooler. For various reasons the case was examined repeatedly, and the conviction was more and more certain in regard to the existence of a popliteal aneurism. All the members of the visiting staff, as well as many others who saw the case, the majority of them expert auscultators, agreed in that opinion; in fact, there did not appear to be a reasonable chance for an error in diagnosis.

The treatment by flexion was commenced on March 17th. The immediate result was the diminution of pulsation in the tumor and the bruit. This failing Esmarch's bandage was applied, but this in turn became so painful that it had to be removed. Next pressure was resorted to by relays of medical student, two or three hours at a time, and then pressure by means of an artery compressor.

Although the tumor diminished in size and became harder, it was quite evident that a cure was not to be expected by these means. These efforts were kept up for nine days, at the end of which time the femoral artery was ligated in Scarpa's space. As soon as the vessel was ligated all pulsation ceased, and the tumor subsided considerably.

After the lapse of six days, the patient complained of violent pain in the joint, which latter became very much swollen and red. It was then supposed that suppuration was going on in the aneurismal sac.

On May 1, Dr. Weir came on duty. At that time fluctuation was distinct over one portion of the tumor. The needle of the aspirator was introduced and blood withdrawn. A poultice was applied, which was the means of giving some relief.

May 23d, a bistoury was introduced into one of the fluctuating points, and gave exit to a considerable quantity of pus and blood. For the first time there was enlargement of one of the ganglia of the groin and this, with the extension of the growth upon anterior portion of the thigh, aroused the suspicion of the existence of a tumor other than aneurismal. Some days after this, near the site where the bistoury had been introduced, the tumor ruptured and gave exit to a large quantity of blood and pus. The pain in the limb continued; the patient began to have a cough and was evidently running down. Dr. Weir amputated the thigh on June 22d, but unfortunately the patient died of phthisis Aug. 5th.

On examining the tumor after the removal of the limb, a portion was found filled with a material which resembled laminated fibrine. Besides this there was new growth on the anterior portion of the femur which invaded the cancellous structure, occasioning an oblique fracture of the lower portion of the femur. The popliteal artery was posterior to the tumor, and independent of it.

Dr. MASON, in conclusion, remarked that although the error in diagnosis was a grave one, he did not see how he could guard against its repetition under similar circumstances.

Dr. FLINT asked if there was a double systolic murmur over the tumor.

Dr. MASON answered in the affirmative.

Dr. FLINT remarked that the opinion at one time prevailed, that double murmurs never occurred under these circumstances, except when an aneurismal tumor existed. Experience, however, had proved the contrary to be the case.

Dr. HEITZMANN remarked that it was of the greatest importance to examine the lungs in these cases, as in some the latter were affected it was presumptive proof against the existence of aneurism. At least Rokitsansky had shown that aneurisms of the aorta and phthisis do not coexist.

Dr. FLINT thought that the differences of age in which the diseases respectively occurred might in a measure account for this, phthisis occurring usually under thirty years, and atheroma much later.

#### FORWARD DISLOCATION OF HUMERUS AND FRACTURE OF THE GREATER TUBEROSITY.

Dr. RIPLEY presented the upper portion of the humerus, removed from the body of a gentleman aged fifty-four years, who died of phthisis two years after an injury of the shoulder by a fall from his carriage. Immediately after the accident the patient consulted a homeopathic practitioner, by whom he was referred to a homeopathic surgeon. The latter gentleman diagnosed a dislocation of the shoulder, and attempted to reduce it. Assuring the patient that he had succeeded, he bound the arm in a sling and let him go. Dr. Ripley was sent for some time after to treat the patient for an ulcer of the leg. Noticing the position of the elbow of the injured side, he expressed his doubts that the dislocation had been reduced, giving it as his opinion that the head of the bone was still anterior to the glenoid cavity, and that there was also a fracture of the surgical neck. Dr. Sayre was called in consultation. He confirmed the diagnosis of dislocation, but thought that there was a fracture of the head of the scapula. The man refusing to take ether, nothing was done. He, however, gained a very useful limb in time, the only thing which troubled him being his inability to comb the hair on the back of his head.

At the autopsy it was found that there was a forward dislocation under the clavicle, with fracture of the greater tuberosity. When the specimen was removed there was no opportunity to examine the exact relations of the parts, although the greater tuberosity was discovered moving easily and naturally under the coracoid process, the head of the bone having formed a new glenoid cavity between the first and second ribs.

#### MYSTERICAL VAGARIES—STRANGE SUBSTANCES IN THE RECTUM.

Dr. HEITZMANN presented some macerated vegetable material removed from the rectum of an hysterical female. On microscopical examination it was proved to have been introduced by unnatural means. After the patient was informed of this opinion, the peculiar disease of which she supposed herself suffering was at once arrested.

#### GLASS IN BLADDER.

Dr. BRIDGON, in this connection, related the case of a woman who was in the habit of introducing bits of

glass into her urethra for the sake of being a patient in the different hospitals of New York. At the time she was an inmate of the Presbyterian he had extracted pieces of glass from the urethra, and afterwards narrowed its orifice by encircling it with a silver wire suture. This obviated the necessity of any further operation.

#### EPITHELIAL TUMOR OF LABIUM.

Dr. HINTON presented an epithelial tumor of the right labia which he had removed by operation from a woman, aged sixty-seven years, a patient in the Presbyterian Hospital. About eight months ago, when the growth first made its appearance, the patient was teased with a desire to urinate four or five times during the night. At the time of its removal it was twice the size of a chestnut, was ulcerating, and occupied the whole labium. The operation consisted in the removal of the latter, and the parts were brushed over with a red-hot iron. In the course of four or five days the sloughs separated, and the wound promised to heal kindly. The microscopical examination of the growth was made by Dr. Satterthwaite.

#### A LARGE CRANIUM.

Dr. BRIDGON exhibited, on behalf of Dr. Metcalfe, who in turn had received the specimen from Dr. W. H. Geddings, of Aiken, S. C., the completely ossified skull of a male negro, aged seven years. The intellect was not markedly defective. The following were the measurements of the cranium:

Circumference, 25 $\frac{1}{2}$  inches; from foramen magnum to fronto-nasal suture, 20 inches; from one zygomatic process to the other, 17 $\frac{1}{2}$  inches; from one fronto-malar suture to the other bisecting parietal bosses, 20 $\frac{1}{2}$  inches.

Dr. HINTON referred to the case of a young boy, now living on Seventh avenue, who had a skull larger than the one shown, and who, as far as he could see, was ordinarily intelligent. The body then went into Executive Session.

## Correspondence.

### EDGEWISE DISLOCATION OF THE PATELLA.

TO THE EDITOR OF THE MEDICAL RECORD.

Sir:—Having this moment received the number of the Record, dated Dec. 30, 1876, I hastily opened it with my usual expectation of finding something new and interesting, and, as is my custom, read the "Contents" first. The case of Dr. A. N. Dougherty, of "Edgewise Dislocation of the Patella," interested me, and on turning to it, found it to be so nearly the counterpart of a case which came under my observation about four years ago, that it may prove worthy of record. The patient was a merchant of this city who, in company with a few friends, were showing a stranger *the sights*. On entering a house of "easy virtue," my patient was met by one of the inmates, and invited up-stairs. He at once assented, and on attempting to ascend the steps was playfully caught by the right foot by one of his friends. He very naturally struggled to liberate himself, and in doing so fell to the floor, a distance corresponding with the height of three or four steps of an ordinary stairway. It was at once observed that he was seriously injured, and I was summoned to attend. On my arrival, about

fifteen minutes afterwards, I found the patella of the right knee dislocated edgewise, exactly as described by Dr. Dougherty, and I reduced it in precisely the same manner. Having had no precedent to govern me, and having forgotten the instructions given upon the subject by the celebrated authority quoted by Dr. Dougherty, it occurred to me that the forcible straightening of the leg might, the system still suffering from shock, so relax the tense muscle as to enable me to reduce the dislocation. This was accordingly done, and on the application of considerable pressure to the projecting edge of the patella, reduction was effected with an audible snap. A high degree of inflammation ensued, necessitating the application of ice-bags. Subsequently, a straight splint was applied, in order that my injunction of *absolute rest* might be observed. After the expiration of three weeks an elastic cap was applied, and the patient allowed to leave his room. No untoward event followed, and he made a good recovery.

If Dr. Dougherty's case be the fourteenth on record, this will probably be the fifteenth. Be this as it may, neither case detracts from the merits of the instructions given by Professor Gross, for the principles upon which he has recorded his views are *correct*.

W. R. CLYNESS, M.D.

SACRAMENTO, CAL.

## ERYSIPELAS AND PUERPERAL FEVER.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In my communication respecting "Erysipelas and Puerperal Fever," appearing in the MEDICAL RECORD of January 13, 1877, I find myself reported as saying, first and second lines, "respecting the etiology of erratic erysipelas and puerperal fever," which should read, *respecting the etiology of erysipelas and puerperal fever*; also in the twenty-first and twenty-second lines, "The case proved to be one of well-marked phlegmonous erysipelas," which should read, *The case proved to be one of well-marked erratic erysipelas, etc.*

Yours respectfully,

WALTER B. CHASE, M.D.

WINDHAM, N. Y., January 15, 1877.

[It is proper to state that the error arose from a misconception as to a correction of the original manuscript.—Ed.]

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Some time in '64 or '65, I think it must have been, I communicated a case to your paper, of the same character as that of Dr. Chase's in the last number. I had then but recently commenced practice in New York, and had charge of an out-door district—Demilt Dispensary. A young woman, within a day or two, if I remember rightly, after a comfortable confinement, was attacked with erysipelas, which involved in its course the whole head and face. I watched her with great interest; but what I feared and half expected never came, and she recovered, as most of our uncomplicated cases of idiopathic erysipelas do recover. I made inquiries quite largely among the profession of New York at the time, but found no physician who had had a similar experience. It was at the suggestion of several physicians that the report was given to the RECORD; nor have I ever since, until now, encountered another such case in practice or in print.

Will you allow me room for one more point? Just a year ago I was attending a little boy sick with erysipelas of face and head. His mother insisted upon being his sole nurse, and watching by his bed day and night. When he had been sick for full ten days, the

mother was overwhelmed with a sudden illness, which carried her off in forty-eight hours. Nothing about her brief sickness was comprehensible to me, and an autopsy was solicited and performed. Upon opening the abdomen, the cause of death was at once apparent. There was almost universal peritonitis, of which, as I need not add, there had not been any of the ordinary symptoms during life. *She was menstruating when stricken down.* Query.—Was there any etiological connection between erysipelas, menstruation, and peritonitis in this case?

Yours respectfully,

HENRY M. FIELD.

NEWTON, MASS., Jan. 14, 1877.

## ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from January 14 to 20, 1877.*

McKEE, J. C., Surgeon. Assigned to duty as Medical Director of this Department, relieving Surgeon Magruder. G. O. 1, Dept. of Arizona, Jan. 1, 1877.

GIBSON, J. R., Asst. Surgeon. Assigned to duty at Fort McPherson, Nebraska. S. O. 5, Dept. of the Platte, Jan. 12, 1877.

AINSWORTH, F. C., Asst. Surgeon. Assigned to duty as Post Surgeon at Camp Grant, A. T. S. O. 1, Dept. of Arizona, Jan. 2, 1877.

PRICE, C. E., Asst. Surgeon. To accompany battalion of 4th Artillery to San Francisco, Cal. S. O. 5, C. S., Dept. of the Platte.

WOOD, M. W., Asst. Surgeon. Assigned to duty at Camp Robinson, Nebraska. S. O. 5, C. S., Dept. of the Platte.

ROSSON, R. L., Asst. Surgeon. Assigned to duty at Camp Thomas, A. T. S. O. 1, C. S., Dept. of Arizona.

SAMUEL Q. ROBINSON, M.D., and WM. B. DAVIS, M.D. (approved candidates), appointed Assistant Surgeons, U. S. Army, to date from January 9, 1877.

## Medical Items and News.

CONTAGIOUS DISEASES.—Comparative statement of cases of Contagious Disease reported to the Sanitary Bureau, Health Department, for the two weeks ending January 20, 1877.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-Spinal Meningitis.	Measles.	Diphtheria.	Small-pox.
Jan. 13.....	1	6	64	1	6	39	1
" 20.....	0	4	53	2	8	31	0

MORTALITY OF DIFFERENT DISEASES IN DIFFERENT MONTHS OF THE YEAR 1876.—Dr. John T. Nagle, Deputy Registrar of the Health Board, has compiled a very elaborate table of all causes of death during the past year in the city, showing the effect of temperature and meteorological changes upon monthly mortality.

He concludes that "the month of January was one of the most fatal months to persons suffering with small-pox, diphtheria, membranous croup, and puer-

al diseases; February, to those who had small-pox and whooping cough; March, to measles, puerperal cases, phthisis pulmonalis, bronchitis, pneumonia, palsy, Bright's disease, and nephritis, and persons twenty years old and more; April, to scarlatina; May, typhus fever; June, to suicides; July, to diarrhoeal cases, alcoholism, serofula and marasmus, tubercular meningitis and hydrocephalus, encephalitis and antile convulsions, diseases of the brain and nervous system, drowning, sunstroke, and diseases of children under 5 years of age; August, to suicides; September, typhoid fevers, and December, to cancer and disease of the heart. The actual mortality for the year 1876 was 29,152, of which 7,170 were under 1 year, 10,692 under 2 years; 14,208, or 48.74 per cent. of the total were under 5 years, and 1,739 were persons 70 years and more. The month of July, however, is the healthiest month of the year, having caused 4,164 deaths, and is especially destructive to children under years, and particularly those suffering from diarrhoeal complaints: the number under 5 years that died during this month was 2,708, of which 1,713 were from diarrhoeal diseases; August and March following next, with 2,750 and 2,729 deaths, respectively; the former month caused 1,572 deaths in children under 5 years, of which 895 were from diarrhoeal diseases, and the latter month caused 1,238 deaths of children under 5 years, of which but 34 were from diarrhoeal diseases. Hence, while the winter months produced a very small number of deaths from these causes, they contributed largely to the excess in the summer mortality. Most prominent of all the causes of death for the year, phthisis pulmonalis, or consumption, stands first on a mortality list, 4,194 persons having died from this sadful disease, which has as yet baffled all medical skill for its cure. This disease was most fatal in the month of March, and least fatal in June, having caused 55 deaths in the former and 309 in the latter month. Following in numerical order are diarrhoeal diseases, which caused 3,782 deaths, of which 3,412 were children under 5 years of age. Diseases of the brain and nervous system caused 2,664; pneumonia, 2,542; phthisis, 1,750; bronchitis, 1,214; Bright's disease and nephritis, 1,132, and disease of the heart, 993, or 3.67 per cent., or more than three-fifths of the entire yearly mortality was from these 8 diseases.

The deaths, as they are distributed by wards, according to the table here presented, will also prove instructive in showing the effects of density of the population and overcrowding upon the mortality. Thus, it will be seen that in the fifteenth ward, with a population—according to the State census, taken in June, 1875—of 25,543, the total deaths were 467; while a fourth ward, with a smaller area, and a population of 26,471, had 733 deaths, or with but 928 more inhabitants, it had 266 more deaths.

**PREVENTION OF SCARLET FEVER.**—The Board of Health of Boston has caused a copy of the following circular to be sent to every householder in the city, and in a previous circular, physicians are directed to report once every case of sickness from this cause:

BOSTON, Jan. 9, 1877.

**SCARLET FEVER.**—The Board of Health issues the following circular of recommendation with the hope that those not familiar with the care of scarlet fever, may be benefited thereby: Scarlet fever is like small-pox in its power to spread readily from person to person. It is highly contagious. The disease shows its first signs in about one week after exposure, as a general rule, and persons who escape the illness during a fortnight after exposure, may feel themselves safe from

attack. Scarlet fever, scarlatina, canker, rash and rash fever are names of one and the same dangerous disease. When a case of scarlet fever occurs in any family, the sick person should be placed in a room apart from the other inmates of the house, and should be nursed as far as possible by one person only. The sick-chamber should be well warmed, exposed to sunlight, and well aired. Its furniture should be such as will permit of cleansing without injury, and all extra articles, such as window drapery and woollen carpets, should be removed from the room during the sickness. The family should not mingle with other people. Visitors to an infected house should be warned of the presence of a dangerous disease therein, and children, especially, should not be admitted. On recovery the sick person should not mingle with the well until the roughness of the skin, due to the disease, shall have disappeared. A month is considered an average period during which isolation is needed. The clothing, before being worn or used by the patient or the nurse, should be cleansed by boiling for at least one hour, or, if that cannot be done, by free and prolonged exposure to out-door air and sunlight. The walls of the room should be dry-rubbed, and the cloths used for the purpose should be burned without previous shaking. The ceiling should be scraped and whitened; the floor should be washed with soap and water, and carbolic acid may be added to the water—one pint to three or four gallons. The infected clothing should be cleansed by itself, and not sent to the laundry. In case of death from scarlet fever, the funeral services should be strictly private, and the corpse should not be exposed to view. Because children are especially liable to take and spread scarlet fever, and because schools afford a free opportunity for this, the Board of Health has excluded from school every child from any family in which a case of the disease has occurred, and has decreed that the absence shall continue four weeks from the beginning of the attack, except in cases subject to the discretion of the Board, and that the scholar, to be readmitted to his school-room, must have the certificate of a physician that the required time has passed. The proper blanks can be obtained at this office on application.

C. E. DAVIS, *Clerk.*

**THE EYE AND EAR INFIRMARY.**—The fifty-fifth annual meeting of the New York Eye and Ear Infirmary was held, Jan. 16, at the Infirmary, at Second avenue and Thirteenth street, Royal Phelps presiding. The following officers were re-elected: President, Royal Phelps; Vice-Presidents, Benjamin H. Field and A. Du Bois, M.D.; Treasurer, John L. Riker; Secretary, Charles M. Allen, M.D. Three vacancies in the Board of Directors were filled by the following gentlemen: Wm. E. Dodge, John Carey, Jr., and Jacob D. Vermilye. The Treasurer announced the following bequest and gifts: Estate of Thomas Barron, \$5,000; B. F. Wheelright, \$1,000; special gift of \$50 from James S. Stokes, to provide spectacles for indigent patients; Mrs. A. T. Stewart, \$2,000; F. W. Mayer, \$100; J. J. Astor, W. C. Schermerhorn, J. B. Cornell, Rutherford Stuyvesant, J. D. Vermilye, and John Carey, Jr., contributed each \$150, constituting them life governors. The annual report showed that 9,701 patients had been treated during the past year. Resolutions of respect and regret were adopted with regard to the deaths of Edward H. Owen, late legal adviser to the Board, Dr. George Wilkes, First Consulting Surgeon, and Dr. Herman Althof, Executive Surgeon. Dr. Charles M. Allen was elected Consulting Surgeon in place of Dr. Wilkes.

**PREVENTION OF FIRES IN SCHOOLS.**—The Building Committee of the Board of Education of this city, to whom was referred a resolution, passed in December last, suggesting the necessity of drilling the children of the public schools in the proper conduct to be observed by them in case of fire, offered the following resolutions, which were adopted:

*Resolved*, That this Board deem it expedient to place Babcock's fire extinguishers in the several school-houses; and,

*Resolved*, That the Trustees of the several wards be requested to instruct the principals of the several schools and departments under their jurisdiction to train the pupils by necessary drill, so that they may, on a sudden emergency, be able to leave the building in the shortest possible time, and without confusion or panic.

**DR. GEORGE THOMPSON**, of this city, met with accidental death from poisoning on Monday, Jan. 15, 1877. He was a graduate of the University of Vermont, 1864, was a member of the Medical Society of the County of New York, and Surgeon to the 9th Regiment, N. G. S. N. Y.

**HEATING STREET-CARS.**—The subject of heating the street-cars is being discussed before a committee of the Board of Aldermen. From present appearances, by the time the testimony, pro and con, is taken, the weather will be warm enough to make any heating apparatus unnecessary.

**NITRO-GLYCERINE EXPLOSION.**—Jan. 18, a laborer in Sing Sing, in an attempt to dislodge a can of nitro-glycerine from a hole in the frozen ground, was blown to atoms. Fortunately no others were injured. The excited inhabitants were busy for a long time in gathering the fragments of the body, one of which was found one hundred and fifty yards from the scene of the accident.

**A PROPOSED NEW CITY CHARTER.**—It is said a bill, amending the New York charter very materially, has been drafted by "a committee of city taxpayers," which provides that the office term of the Dock Commissioners, the Police Commissioners, Health Commissioners, and the Charity Commissioners, shall terminate ten days after the passage of the act, the Mayor to appoint their successors. The Police Department is, under the bill, to be composed of two "public commissioners of the city of New York," and the Health Board to control the Street-cleaning Bureau.

**CAPACITY OF THE HUMAN STOMACH.**—The capacity of the human stomach is estimated at two quarts. The recent exploits of a couple of Londoners prove, however, an exception to the rule. By a careful estimation of the quantity of food and liquor taken during a so-called spree, it would seem that each stomach held two gallons, or else there were no pyloric valves. The prospects for soon settling the question by an autopsical examination were at last accounts quite promising.

**INEBRIATE ASYLUM, BINGHAMTON, N. Y.**—The annual report of the Inebriate Asylum at Binghamton shows that from May 1, 1867, to Dec. 31, 1876, 2,065 patients were treated. More than one-half of these were permanently cured. The receipts during the year, inclusive of cash on hand, amounting to about \$7,000, were \$43,714.25; the expenditure \$38,319.03; cash on hand, \$5,395.22.

**KENTUCKY SCHOOL OF MEDICINE.**—Dr. J. A. Octerlony has entered suit against the Kentucky School of Medicine for the recovery of fees which he claims are

due him as professor in that institution for 1876. He avers that he received only five dollars, when he should have received seven or eight hundred. Possibly the deficiency may be explained as one of the results of the beneficiary system for which the school in question has gained such an unenviable notoriety.

**OPERATIVE FEES TO GENERAL PRACTITIONERS.**—A writer in the *Lancet* claims that fees for attendance upon operations should be paid to general practitioners, when assisting, at the time the services are rendered; that they are always extra and special in their character, and are entirely independent of previous or subsequent attendance upon the patient.

**BALTIMORE MEDICAL AND SURGICAL SOCIETY.**—The following officers were elected for the ensuing year: Dr. W. W. Murray, president; Drs. R. W. Mansfield and S. W. Seldner, vice-presidents; Drs. W. Brinto and C. C. McDowell, secretaries; Dr. D. W. Cathel, treasurer; committee of honor, Drs. J. S. Lynch, A. B. Arnold, and L. B. Winternitz; committee of lectures and diseases, Drs. T. B. Evans, J. J. Caldwell and W. J. McDowell; executive committee, Drs. J. Morris, J. Reiberger, and A. F. Erich.

**THE LATE DR. GEO. WILKES.**—At a meeting of the New York Medical and Surgical Society, held December 30, 1876, the following resolutions were passed:

*Resolved*, That the members of the Society have heard with deep regret the intelligence of the death of their late associate, George Wilkes, M.D.

*Resolved*, That we cherish his memory as that of true friend, an upright and honorable member of our profession, a good citizen, and an honest man.

*Resolved*, That we recommend as worthy of praise and imitation his benevolence and disinterested kindness to the poor.

*Resolved*, That we sympathize with his family in the bereavement which they have sustained.

*Resolved*, That a copy of these resolutions be sent to the medical journals and to the family of the deceased.

JAMES R. WOOD, M.D., *President*.

R. F. WEIR, *Secretary*.

**CHIEF OF THE BUREAU OF MEDICINE AND SURGERY OF THE NAVY.**—Upon the retirement of Surgeon-General Joseph Beale, Chief of Bureau of Medicine and Surgery of the Navy Department, on March 3d, it is stated that Surgeon C. J. Stuart Wells will be promoted Chief of that Bureau.

**TENEMENT-HOUSES.**—More than half the deaths in this city in 1876 occurred in tenement-houses, and yet not more than one-tenth of the population live in them.

**SMALL-POX IN NEW ORLEANS.**—Since the 1st of January 117 new cases of small-pox have been reported to the Board of Health, including one case from the State-house. Several cases are reported among the troops in the Custom-house.

**THE POOR OF NEW YORK.**—George Kellock, Superintendent of the Out-door Poor at the Department of Charities and Correction.—About 1,600 people apply daily for aid. With 1,700 families depending on him for daily bread, and with scores of fresh applications daily, the West Side Relief Association appeals to the public for groceries and clothing for distribution to the deserving poor. It does not ask money now, but would prefer gifts of provisions and cast-off clothing which can be given out at once. Unless gifts come speedily, the Association will be compelled to close its doors.

## Original Communications.

## ON SOME CONDITIONS, PHYSICAL AND RATIONAL, IN EFFUSIONS OF THE PLEURA.

CONSIDERED WITH REFERENCE TO THORACENTESIS, FOLLOWED BY AN INQUIRY INTO THE CAUSES WHICH HAVE PRODUCED SUDDEN DEATH AFTER THIS OPERATION.

By BEVERLEY ROBINSON, M.D.,

SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL (DEPART. OF THE THROAT), ONE OF THE PHYSICIANS TO CHARITY HOSPITAL, NEW YORK.

## PART II.

THE idea that the operation of thoracentesis, irrespective of the entrance of air into the pleural cavity, causes the liquid to become purulent is based upon an erroneous hypothesis, proclaimed many years ago by Watson and Stokes. It is a belief, unfortunately, too, which amongst practitioners of Great Britain has been accepted and adhered to by many, as being perfectly reliable, on account of its origin. And yet it is one which has never been established, either by general statistics or by individual examples, closely observed. What the precise or final cause of this change of fluid, from serous to purulent, is, we do not yet know; but why attribute it to the trocar? Convincing proofs do not sustain such an admission, and reasoning by analogy only makes it a less probable cause.

If we consider, for instance, what takes place after the puncture of the abdomen, even though several operations be performed, we find that the liquid still remains serous. Why, then, in effusions of the chest, should we have a different result? It is proper, when a primary puncture is serous, and a second purulent, to search for the cause, or explanation of this change; but why accuse the operation? Experiments on animals, and numerous clinical histories, prove that puncture of the chest does not make the effusion purulent; \* why not, therefore, consider, what is evidently of far more essential importance, viz., certain special individual and organic conditions, still badly determined, but nevertheless exerting a considerable and definite action?

We know, for example, perfectly well, when a state of great feebleness arises in the course of an acute pleurisy, that the liquid frequently becomes purulent. In a similar manner, we are aware that, owing to the influence of a cachectic condition, such as occurs near the fatal termination of certain chronic conditions (cancer, tubercle, etc.), serous fluid in the pleura spontaneously becomes purulent. Among the sequences, too, of an acute febrile affection, such as scarlatina, measles, typhoid fever, and still others, it is not very unusual to encounter the change just mentioned. Why certain general conditions, however, and more especially those in which the functions of nutrition are seriously implicated, lead directly towards purulent effusions rather than others, this is the knotty point which medical science has not hitherto unravelled.†

Again, we could cite numerous instances where thoracentesis has been the means by which a purulent

effusion has been rapidly cured. Aram,\* Roe,† Markowitz,‡ Bouchut,§ Sparks,¶ and others have reported such cases. It seems to me, therefore, to be somewhat irrational, on the one hand, to admit that puncture with a capillary trocar has occasioned a purulent effusion, and, on the other, has been the effective means of curing it. Now the cases of cure are certain, and contain no elements of doubt; whereas the cases of the former kind are but hypothetical, or at best sustained by very insufficient histories and statements.

But with the improved instruments of Potain, or Dieulafoy, and by exercising a very little care, the entrance of air into the pleural cavity may ordinarily be avoided. Occasionally, however, there may be a backward suction towards the chest, with the use of the apparatus just mentioned, which may draw some globules of air into it. These globules come from the tube connecting the canula with the syringe, or bottle of the aspirator, where a vacuum should be made previous to commencing the operation. If the still more improved form of aspirator, described by Fraentzel,¶ be employed, I hold, with this learned author, that the introduction of air into the pleura is absolutely impossible. Fraentzel's apparatus has the advantage over Potain's, in that it possesses a cock at the lateral tube, and India-rubber plates, pressed in between the screw cylinder, by which the stylet is shut in absolutely air-tight and can be moved backwards and forwards without the admission of any air from without into the pleural cavity.¶

*d. Thoracentesis should be performed in all cases as soon as the quantity of effusion is appreciably large.* Many of the preceding arguments might again be employed to sustain this proposition, and others, too, which are already worn by the repeated use of writers on this subject.

In order to avoid vain repetition, I shall not speak of any of them, further than to emphasize the fact that similar arguments may be given for the withdrawal of a small quantity of liquid from the pleura, as if it were somewhat larger. From certain points of view, the damage threatened to the integrity of, or normal conditions within the chest cavity, are, without doubt, less considerable. But because the morbid changes are neither extensive nor very intense in character, their existence is none the less an actual evil and a future menace. For both these reasons, therefore, they should be got rid of in the surest and most rapid manner, consistent with the welfare of the patient.

In a very interesting letter to Dr. Albutt, of Leeds, England, published in the *Practitioner* for April, 1877, Dr. Bowditch, of Boston, remarks that he has perhaps erred in not operating immediately after finding fluid effused, even to a moderate amount. "My reason," he adds, "does not give me valid grounds for delay, and certainly my experience of the effects of the operation suggests nothing but that pleasant results would follow it whenever performed." Can any statement be more persuasive than this, in support of my own opinion? For be it remembered, that it is a textual citation of the declared conviction of one who, among living authorities, has had possibly a wider experience of the operation of thoracentesis than any other practitioner of whom we have cognizance. There is one objection, however, against puncture in very small effusions, which should be combated in this place, viz., the accidental wound of the

lung. Already, on several occasions, the lung of man has been punctured with a small capillary needle (No. 1), and under no circumstances has the slightest accident taken place. Besides, experimental punctures have been frequently made, and, as it has been shown, without untoward consequences resulting from them. Occasionally, it is true, a patient has expectorated a small number of sanguinolent sputa, after the lung has been wounded; but this is an insignificant phenomenon, or one, at all events, without gravity, and in cases where pneumonia exists concomitantly with pleuritic effusion, a local bleeding thus performed may prove to be useful. In one recorded case, even though the puncture of the lung was undoubted, and repeated on three successive occasions, the painful sensation of a pointed instrument entering the pulmonary tissue was the only unpleasant consequence of the use of the aspirator.\*

Moreover, according to Dieulafoy, the function of the lung is the condition, in the event of a mistake, which alone will allow the diagnosis to be established with certainty.†

It was formerly conceded by many that the principal indication for operating was found in the degree of dyspnoea. If the dyspnoea were great, it was thought best to operate, if only moderate, we should watch and wait. Unfortunately, such a system has frequently led to unhappy consequences. Though great care had been exercised by the attendant physician, orthopnoea has suddenly declared itself, and a fatal result has followed before adequate aid could be afforded. Already I have shown what valuable signs may be furnished by auscultation and percussion. Now, if these physical methods of investigation inform us positively that the effusion is increasing rapidly, no matter what may be the degree of oppression, whether it be slight or intense, *the formal indication is to operate*, for the dyspnoea is no guide to the quantity of the effusion. And while there are frequent cases where the dyspnoea is intense and the effusion small, there are others where the oppression is slight, and yet the physical signs of a large effusion can be unerringly discovered. When, however, we are assured of the existence of a large quantity of fluid in the pleural cavity, and at the same time we find our patient laboring from considerable oppression and difficulty of respiration, we have, in these last symptoms, additional reasons for undertaking operative measures. If, however, an abundant effusion be diagnosed, and yet the dyspnoea is very moderate, or, indeed, altogether absent, we should not, on this account, be deterred from an operation. The price of safety, let it be fully and clearly appreciated, is in the immediate use of the aspirator and the withdrawal of the greater portion of fluid in the chest. Finally, then, physical signs must be implicitly relied on as regards the opportunity of an operation, for rational signs are at best unreliable, inasmuch as they are not necessarily present. In this place it behooves me to bring clearly before your minds the question, whether or not, thoracentesis can be held fairly responsible for causing sudden death in cases of pleuritic effusion. In order to estimate this subject properly, we should keep steadily in view the rare facts, amply circumstantiated, however, that instantaneous death may and does follow in the natural course of pleurisy, and when no operation whatever has been performed. In this way we shall avoid attributing to surgical interference what is one of the occasional accidents in the disease

under consideration. Whilst, however, we should exercise due and even severe scrutiny, before accepting evidence as valid, against puncture of the chest, if it be indubitably proved that this procedure has been the efficient cause of fatal complications, we should not allow any predilection of ours to bias us against what are just conclusions evolved by accurate analysis. But to analyse rigidly and afterwards make the manifest or essential deductions which proceed from our inquiries, asks for familiarity with all the elements and bearings of each case. Now, such knowledge has not always been possible in the instances I am about to examine.

Occasionally sudden death has occurred during, or shortly after thoracentesis has been performed, and for various reasons no post-mortem has been made. Several times, although the autopsy was carefully made, the cause of death has not been discovered at all, or indeed, owing to the fact that one or more sufficient causes of death have been recognized, our mind remains in doubt as to which was the really proximate cause, and how far, too, the others actually present exerted a modifying and important influence. Still, numerous facts remain, which permit me to affirm, on the one hand, that thoracentesis has frequently been a concomitant fact without probable influence over the fatal termination, and that death was sure to occur though the patient had never been operated on; on the other, that it undoubtedly was the determining cause in producing sudden or rapid death; but in nearly all these cases this result would have been avoided if our present knowledge had been put in requisition, and certain prudential methods of execution been strictly adhered to. The foregoing remarks being received for the time as indisputable, I shall now briefly abstract from the cases in point sufficient matter to enable me to establish my affirmations.

In more than one case reported, death could be justly attributed to an embolus of one of the middle cerebral arteries. Such are those referred to by Vallin, in a memoir read before the Medical Society of the Hospitals of Paris, in 1869, by Duroziez, in an article published in the *Gazette des Hôpitaux*, for 1870, and by Forster,\* in a chapter upon embolisms after thoracentesis by aspiration, written in 1874. Very lately this subject has been learnedly reviewed by Desnos, in the *Gazette Médicale*.† In these instances, fainting and loss of consciousness took place, and was rapidly followed by hemiplegia, epileptiform convulsions, and death. The emboli originated most probably in thrombi, which had been formed in the pulmonary veins, owing to the compression of the lung-structure by a large pleuritic effusion, or in the heart affected with pre-existent valvular or fatty degeneration.

It has been shown latterly, in every case where convulsions have come on after thoracentesis, they have appeared while the fluid was being injected, and *not* while it was being withdrawn. This fact would appear to indicate that the *injection*, and not the emptying of the chest, had something to do in causing death, and in instances where embolisms have been found in different organs at the autopsy, the most rational explanation is that it served to detach a thrombus already formed—sometimes in the heart, more frequently in the pulmonary veins. But whilst the *injection* appears thus far to be more implicated than the puncture of the chest in occasioning these complications, still, as they may follow puncture also,

\* *Gazette des Hôpitaux*, 1876.

† *Loc. cit.*, p. 214.

\* *Clinical Lectures and Essays*.

† April 22, 1876.

as it seems to me, it is not out of place to consider them. The practical deductions, from recorded examples, are, therefore: (1) to perform thoracentesis before these thrombi have formed; (2) to inject liquid, when required, into the pleural cavity, with very moderate force, and in limited quantities at one time, so as not to increase the pressure upon the pulmonary surface. And, further, they should teach us to beware attributing to these operator procedures fatal consequences which, without them, might possibly have been retarded, but could scarcely have been altogether avoided. For the thrombus once being allowed to form, owing to blamable procrastination in operating, many other circumstances, arising accidentally, or in the usual course of events, might serve to detach it, and thus prove to be an equally efficient cause of death. The nature of the fluid used in injection of the pleural cavity seems to be without influence in causing the development of accidents. The manner of using it is alone of importance; and this is a point I would again strongly emphasize. Do not inject with too much force, nor in too considerable quantity at any one time; for, besides increasing pressure upon the lung directly, which, as stated, will have of itself a decided tendency to loosen a thrombus if formed, cough thus produced will exert an injurious action towards a similar untoward result.

In those cases where the above phenomena have been observed, and where no embolism or thrombi have been found, in spite of a very thorough examination of heart, lungs, brain, and especially the medulla oblongata, the efficient cause of the convulsions has been differently interpreted. Conpland\* has considered them to be due to the excitation of a puncture in a very nervous patient. What is meant precisely by "nervous patient" is not stated; and as to the exact signification intended by the use of this term, we are left to conjecture. Raynaud, with somewhat more reason, has claimed that irritation of the inner aspect of the walls of the chest cavity is sufficient to cause death by reflex excitation. In Raynaud's cases there is no history of epilepsy, and, though the urine had been examined shortly before the operation, no albumen was found. Uremic convulsions may be, therefore, fairly excluded, and a direct relation of causality may be established between the operation and the fatal termination.

But what was this operation? Was it simple puncture followed by withdrawal of fluid? No; it was, again, singular to relate, puncture of the chest followed by repeated injections of tepid water through a canula into the inflamed pleura. These injections were at first innocuous. After a time the purulent area in the chest cavity had considerably diminished, and it was at this stage the epileptiform accidents took place. They were apparently brought on by a greater pressure or traction of the phrenic nerve at its diaphragmatic extremity from the injections. And this is explained by the fact that, at the period alluded to, the superior surface of the diaphragm represents the greater portion of the internal surface of the injected cavity, and on account, also, of its mobility supports mainly the effort exerted by the aqueous fluid. The irritation effected is transmitted by the phrenic nerve in a centripetal direction to the medulla oblongata—the excitation of which produces, as we are aware, epileptiform and syncopal phenomena. If Raynaud's explanation of death in certain cases, after repeated injections of the pleura, be correct, it may lead to a more prudent use of them, and even contra-

indicate them altogether in cases where the pleural cavity has become very small. But does it in any manner affect the propriety of puncturing the chest so as to let out the liquid contained in it? But death may result from other causes than those just mentioned. In a case reported by Dr. Ernest Legendre (*Gaz. des Hôpitaux*, 1875), fifteen days after the beginning of an attack of acute pleurisy, thoracentesis was performed, and about three litres of fluid withdrawn. In a very short time after the operation, dyspnoea recurred, copious secretion into the air passages took place, cyanosis appeared, and death resulted from asphyxia in a few moments. The asphyxic state was occasioned here, no doubt, by rapid and overwhelming bronchial effusion in a lung bound down to the spinal column by plastic adhesions, and incapable, therefore, of rapid expansion to its normal capacity. Mr. Temeson\* relates a very similar case to that of Legendre's, where dangerous asphyxia took place after twenty ounces of liquid had been removed. In this example also the lung was unable to expand sufficiently to fill the chest cavity, owing to the formation of pseudo-membranes, and generalized congestion of its structure followed. These facts are corroborated by others mentioned by Behier, Lionville, and Terillon†—all of which prove that death has occurred from the pulmonary congestion and œdema, induced by too rapidly and thoroughly evacuating the thoracic cavity. In these latter instances, however, the pleurisy was complicated by other pulmonary lesion, which doubtless acted as a predisposing cause of a fatal termination. In all of them, if an earlier operation had been performed, or if, when performed, a smaller quantity of liquid had been withdrawn at one time, death in some instances, and dangerous asphyxia in others, would probably not have happened. In a few other recorded cases, sudden death resulted from morbid lesions wholly independent of the pleuritic attack and of the operator treatment employed. In Addison's case it was due to hemorrhage from an ulcer of the stomach; in Liberman's it was occasioned by opening of the right gastro-epiploic artery, owing to extension of an ulcerative process, which had its primitive seat in the duodenum.

Finally, there is a numerous class of cases in which a suddenly fatal termination, probably due to syncope, has occurred. Such an one is that of Legroux, where the patient, on admission into the hospital, presented an immense effusion. The thoracic cavity was completely evacuated by the use of the aspirator, and three-fourths of an hour afterwards the patient died. Death was attributed in this instance to anemia of the brain reacting upon the heart, and to a considerable and rapid flow of a great quantity of blood forcing itself instantaneously into the lungs, liberated by operation, from compression by the effusion. In my mind, there is but little doubt, if the operation had been properly performed in the above case, that a life would not have been uselessly sacrificed. It should have been made slowly and regularly, and soon interrupted, to be again resumed on a future occasion. Instead of that, it was performed hastily and inconsiderately, and without stopping once until the pleural cavity was emptied. No wonder, then, the economy was rudely shaken, that the brain was unable to do without any portion of its natural stimulus, and that the heart was overwhelmed in the midst of an immense effort to throw off pressure it could not withstand.

Again, the mere pain of the puncture has been con-

\* *Br. Med. Jour.*, Nov. 4, 1876, p. 605.

\* *Union Médicale*, Feb. 22, 1876.  
† *Thèse de Paris*, 1873.

sidered sufficient to arrest the heart-beats by reflex action. The case reported by Besnier is one in point. Here the liquid was slowly withdrawn by a trocar No. 2, of Matthew's apparatus, and with almost an excess of every precaution. But a few moments elapsed after the puncture, and only ten ounces of liquid had penetrated the receiving bottle, when suddenly the patient became frightfully pale, and was found to be without movement and pulseless. Energetic flagellations were practised with a towel immersed in cold water, after which two or three feeble respirations were noted, and a little foam appeared upon the lips. Nothing further was observed, and it soon became evident the woman was dead. In this and analogous instances, I can only admit the sufficiency of the apparent cause of death, where there is great failure of heart power. This may exist, as we know, even though the heart is not, in its exterior aspect, seriously affected, or at worst is somewhat enlarged and flaccid. Such cases are frequently encountered in other depressing diseases, owing to loss of nerve-force generated in the cardiac motor centres, rather than to the lack of tonicity in the muscular fibres.

Why, then, should they not be met with in pleuritic attacks, where the vital forces are oftentimes brought very low, owing to the intensity of the inflammatory process, or else by reason of its long duration? Under these circumstances, a cause, usually disregarded, may induce syncope. It may be a slight emotion—it may be a sudden movement in bed, or in raising oneself to a sitting posture, which causes arrest of the heart's action. There is nothing, however, *specific* to cause death in the slight pain occasioned by puncture with a capillary needle. Pain from any other source will do as much in a very enfeebled condition of the organism. Clinical experience is not our only proof of the truth of this statement. Direct experimentation upon animals shows a similar result. Bernard, Chossat, Bernstein, Tarchanoff, and others, have demonstrated facts of the sort beyond peradventure. For in many of these experiments, also, the animal was in a morbid condition, had lost strength and nerve force, either from profound inanition, or from the presence or in consequence of an inflammatory condition. In others the definitive and mortal stoppage of the heart, was adjoined, evidently, to a pre-existing lesion of this organ. To my mind, all these citations, and any just conclusions to be drawn from them, rather support the advisability of an operation, and of an early one, than show contraindications of it. The danger, once again, in the treatment of almost all pleuritic effusions, is in delaying to operate until it is too late. The strength of a patient thus affected will at times rapidly give way, and if we are not convinced of the urgency of the case at the opportune moment, the efficient remedial measure will not be adopted in time, and a pernicious or fatal result may be the immediate consequence of hesitation and delay.

Moreover, from the foregoing remarks, it is at least evident that death follows after thoracentesis according to very different mechanisms. Its pathogenetic relations are, therefore, essentially distinct in many of these instances, which is probable—or they are similar in reality, though apparently various, which is doubtful, not to say impossible; surely, then, and even though we might be forced to concede that thoracentesis is occasionally implicated in the causation of certain effects, there are others which can have no relation with it whatever. Any other view would, of necessity, lead to absolute inconsequences of reasoning and practice. Now, in point of fact, all the following conditions, as already declared, have been

found at one time or another, at the post-mortem examinations of patients who have died during or shortly after puncture of the chest with a capillary needle: Vegetations of the valves of the heart; fatty degeneration of this organ; cardiac thrombosis; pulmonary, cerebral, and spinal embolisms; acute oedema of the lung; pulmonary congestion; ulcer of the stomach; ulcer of the duodenum; and ulceration of the gastro-epiploic artery. Of them all I have found, by rigid and careful examination of the recorded cases, there are very few, even of those apparently due in a measure to the operation itself, which could not have been avoided, or absolutely prevented from occurring. And for this reason I do not hold the operation accountable for them. If we all of us would but operate in season, and with due regard to certain precautionary measures insisted upon in this paper, I feel satisfied we would have rarely a death to deplore in the course of idiopathic pleurisy, and the operation itself would again be almost universally considered as a curative method of great power, and nearly innocuous in its effects, immediate or remote. Hereafter, if, in spite of the light which actual research has thrown upon the interpretation of a complex problem, sudden deaths still continue to occur, it will be time enough to bring discredit upon what, in my estimation, is one of the most positive advances of our day, in the therapeutics of pleurisy with effusion, viz: thoracentesis by means of the pneumatic aspirator. Finally, then, as a practical conclusion of the preceding article, I offer the following to Fellows of the Academy and to the profession in general: Inasmuch as it is proved that puncture of the chest-walls, with a capillary needle attached to the improved aspirator, whenever performed with due precautions against the entrance of air into the pleura, is a perfectly simple and harmless operation, and, further, that any appreciable amount of liquid, irrespective of its nature, is by its presence pernicious, and may become dangerous; therefore I hold that, in all cases of pleuritis, in which fluid is present, we should without hesitation make use of the aspirator to withdraw the morbid effusion.

To this law I shall only affix *one* limitation and *one* exception.

*The limitation is:* Whenever very large or excessive quantities of fluid are present, it is wiser to puncture the chest on two successive occasions, so that all risk of acute oedema of the lung on the affected side shall be avoided.

*The exception is:* If the patient be very much enfeebled and the effusion be small or moderate, we may with advantage delay the operation, during a brief period, until his forces have been somewhat re-established.

By proceeding after this manner, all danger of *fatal syncope*\* will be obviated.

Meanwhile, of course, if the effusion from small, or moderate, rapidly becomes large or excessive, the formal and imperative indication is to operate so soon as possible.

♦♦♦♦♦  
**FIRES IN THEATRES.**—The press of London is unanimous in advocating precautions regarding fires in theatres. The plan of making the scenes and dresses non-inflammable is the one which meets with most favor.

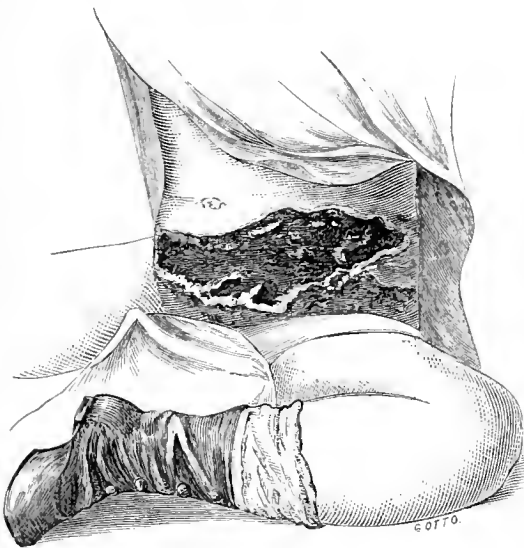

\* In syncopeal states there is anaemia of the brain, which is often successfully treated by placing the patient flat on his back. In view of this fact Marrotte has recommended to operate while the patient is in a half reclining or completely recumbent posture, so that there may be less predisposition to this condition. This practice seems to me judicious.

## A NOVEL AND UNIQUE LESION OF THE INTEGUMENT OF THE ABDOMINAL WALL.

By JOHN S. COLEMAN, M.D.,

AUGUSTA, GA.

I PUBLISH the following notes of an obscure and interesting case with the hope that some one, better versed in neuro-pathology than I am, will unravel the skein:—The patient, a child three years of age, frail and delicate, and with occasional attacks of malarial fever from its birth, was struck, standing, in the lumbar region by the back of a chair in which was seated another child of about the same age. The blow was sufficient to fell it to the floor with the weight of both child and chair upon its loins. At the time the child was not apparently seriously injured. I was not called until the fifth day after the accident. I found the little patient prone upon the bed, with its knees well drawn under the body, and the abdomen supported upon a pillow. The loins were considerably bruised, and the right lumbar region exquisitely tender, swollen, and indurated. At my visit on the morning of the eighth day I noticed that the child was supine in its mother's lap, and that there was a broad dark mark across the abdomen below the umbi-

licus. In the shaded light of the room it had the appearance as though the part had been painted with strong tinc. of iodine. On opening the shutters it presented the bluish-black aspect of senile gangrene, was of irregular form, six inches in length and two inches in breadth; the greater portion say two thirds to the left of the median line, and the other third upon the right. The entire surface bordered by a bright areolar of about half an inch. After a few days minute vesicles appeared upon the central portion: these were soon converted into large bullae, containing fetid sanious serum. The line of demarcation was, after a few days, more fully formed, and the slough rapidly separated. The cicatrization was complete in a few weeks under the constant use of a solution of boracic acid.

What is the pathology of this case?

Note the position of the patient and the smooth

floor against which the abdomen of the child came in contact.

Is it possible that the resilient abdominal wall could be so injured by contact with the floor? I think not. Dr. Weir Mitchell says "Short of a cannon-ball bruise we do not see death of a part caused by blows."

The only tenable theory to my mind is that of an injury to those branches of the vaso-motor system of nerves which supply the portion of the abdominal wall (or rather integument) implicated in the slough, producing infarction or a stasis of the circulation in the part sufficient to cause its death.

## DIGITALIS IN SCARLATINA.

By DANIEL LEWIS, M.D.

NEW YORK.

The following suggestions on the use of digitalis in the treatment of scarlet fever, are offered at the present time, because of the prevalence of the disease in this city, as well as in many other portions of the country.

My attention was first especially directed to this subject by reading the clinical lecture on "The Principle of Physiological Antagonism as applied to the Treatment of the Febrile State," by Prof. Roberts Bartholow, of Cincinnati. (American Clin. Lectures, Vol. II., No. 1.)

His theory is based upon the demonstrated effect of the drug upon the pneumogastric nerve, which action he arranges as follows:

1. Contraction of arterioles and diminished blood supply.
2. Exudation checked or prevented by the heightened tonicity of the vessels.
3. Depression of the temperature.
4. Lessened action of the heart and increased power.
5. Arterial tension raised.

Since the pulse is very rapid in scarlatina, with high temperature, low arterial tension, and embarrassed secretion by the kidneys, the range of antagonism is complete.

Prof. Bartholow declares that, in a considerable experience in the treatment of scarlatina, he has found digitalis uniformly successful, and, taking in a group the ordinary cases of scarlatina simplex and scarlatina anginosa, it is the most efficient remedy we possess.

The chief dangers in such cases are the pyrexia and the consequent degeneration of tissues, and the catarrhal or parenchymatous nephritis, by which elimination by the kidneys is diminished or arrested. Digitalis obviates both these sources of danger by lessening the blood supply to the tissues, and increasing the water in the urine by raising the blood-pressure, and also by its direct action on the Malpighian tufts.

This particular effect of digitalis, in preventing nephritis and other glandular inflammations, has rarely been mentioned by other writers; but an article appeared in the *London Lancet*, January 23, 1869, by Dr. Sydney Fennel, in which he recommended it very highly for lessening inflammation by its effect in reducing arterial tension.

He has used it largely in scarlatina, and says that, when administered early in the fever, the inflammatory action in the glands of the neck subsides gradually. The fever leaves the patient in the usual time, desquamation is very slight, and the chances of chronic nephritis are reduced to a minimum. He also confidently asserts that the infectious character of the disease is lessened by the remedy, if not destroyed.

Thomas, in his article on Scarlatina in Ziemssen's *Cyclopædia* (Vol. II., p. 306), recommends digitalis

for reducing the frequency of the pulse, in doses of seven to thirty grains daily, according to the age of the patient.

I have used this remedy in thirteen consecutive cases of scarlatina.

The age of the youngest patient was ten months, of the oldest twelve years.

There was an abundant eruption in ten of the thirteen cases. Four patients had severe inflammation of the throat, with ulceration, diphtheritic exudation, and considerable glandular enlargement.

The temperature, when the treatment was begun, ranged from 103° to 106½°; pulse 120 to 148.

No suppuration of glands occurred in any case; the temperature was promptly reduced to 102°, or below; the pulse fell to 110-130, and there were no symptoms of nephritis except in a single case. In that one the digitalis had been discontinued, and on the fifteenth day there was a sudden rise in temperature, convulsive movements in the muscles of the left side, and a trace of albumen in the urine.

The digitalis was resumed, and in twenty-four hours all bad symptoms subsided, and the patient made a good recovery.

Four of the patients died; one on the second day, in which eruption was hemorrhagic; two with scarlatina anginosa, on the fourteenth and seventeenth days respectively, in which no physician was called till the fifth day, the immediate cause of death being asthenia; and one after four weeks, who, as I was told, had acute diarrhoea, although I was not again called to attend it.

I may add that otitis followed in three cases, but was so slight as to require little treatment.

The infusion of digitalis was the preparation used in all these cases, in doses of ʒ ss. to ʒ j. every four to six hours. The state of the pulse and temperature being the guides to the dose and period of administration. Prof. Bartholow insists that the genuine English digitalis should be used, and prefers the *infusion*, although a *thoroughly trustworthy tincture* may be employed.

The results of the digitalis treatment in my own cases have satisfied me that it is worthy of a thorough trial; and these notes are published with the hope that others may be induced to use the remedy, and, in due time, report their success or failure to the profession.

## Progress of Medical Science.

**VARIATIONS IN THE NUMBER OF WHITE BLOOD-GLOBULES IN CERTAIN MALADIES.**—DR. HENRI BONNE, of Paris, has been convinced by his researches that there is a constant relation between the production of pus and the presence of an excess of white globules in the blood. Thus, during the evolution of an abscess, there is an excess of the white globules in the blood, but as soon as exit is given to the pus, this excess disappears. In the same way, the white corpuscles are found in excess when a suppurating wound exists. In all the internal febrile maladies, the period of leucocytosis does not seem to correspond to the time of the highest temperature, but to the formation of pus in the organism; thus in typhoid fever, the increase of the white corpuscles is observed at the outset of the disease and at the commencement of convalescence, and in pneumonia it is observed only at the period of hepatization. Dr. Bonne has also observed an evident relation between the eruption of

a group of herpes vesicles and the number of white globules, the latter diminishing when the eruption appeared. The lochial discharge after parturition, and leucorrhœal discharges, are also accompanied by a diminution of the leucocytes. Dr. Bonne publishes thirteen observations, each of them being accompanied by a chart representing the variations in the number of white globules at different periods of the disease.—*Le Progrès Médical*, December 2, 1876.

**TREATMENT OF GLANDULAR SWELLINGS AND ABSCESSSES.**—M. QUINART has had excellent success in twelve cases of adenitis, which he has treated in the hospital of Ghent, by means of blisters. He is not content with attacking simple engorgement of the glandular tissue at the outset with a series of blisters, as Nelaton advised, but he employs the same treatment when pus has already formed. He has in this way succeeded in obtaining resolution of suppurating glands, that have contained several ounces of pus. When the suppuration is already advanced, and threatens to perforate the skin, he punctures the sac, not through the spot where the skin is already thinned, but at the most dependent part of the tumor, where the instrument must traverse a larger extent of healthy cellular tissue. When the sac is emptied, it is covered, whatever its extent, by a blister which overlaps it on all sides by one or one and a half inches. On the next day the blister is dressed with mercurial ointment; as soon as the skin begins to cicatrize, a second blister is applied, and so on. By this procedure M. Quinart has succeeded in curing an abscess that extended from the angle of the jaw to the clavicle, and which contained over ten and a half ounces of pus. An opening was threatened in the centre of the tumor, where the skin was thinned. The tumor was punctured just above the clavicle, and then entirely covered by a large blister. On the next day the little wound was reopened by means of a stylet, and a quantity of serous pus escaped. On the third day the greater part of the sac was closed; the fluid that accumulated in the most dependent part was reabsorbed, and the patient now presents no mark of this immense abscess, except a small cicatrix above the clavicle.—*Gazette Médicale de Paris*, December 2, 1876.

**BUSCH ON INFLAMMATORY AND NECROTIC PROCESSES IN BONE.**—The various stages through which bone passes from inflammation to total necrosis have been carefully studied by Professor Busch, of Berlin, in a series of experiments on animals; and his results throw some light upon these rather obscure processes. His plan was to bore into the medullary canal of a long bone, near the articular extremity, then pass a wire of platinum or iron along the cavity, bringing it out again through a second opening near the opposite extremity. The wire was then heated to whiteness by the galvanic-caustic battery. In a large number of cases various degrees of damage were done to the bone; in some, however, where the platinum wire had been allowed to remain in the bone, no apparent reaction was produced, while the holes through which it had entered were closed. These results tally with those published by Cruveilhier in 1816. Necrosis, the author believes, does not in such cases depend upon the mere presence of a foreign body, but upon some of the physical qualities that are associated with it. The expansion of laminaria, when introduced into the medullary cavity, determines the necrosis; and so with platinum or iron, the chemical or other qualities associated with it are the real exciting agents. Four grades of inflammation, corresponding to the intensity of the cause, were recognized: 1, active inflammation

(ostitis); 2, death of a greater or less extensive lamella from the inner surface of the compact substance (necrosis interna seu centralis); 3, death of the entire thickness of the compact cortex (penetrating necrosis), or of the whole circumference of the bone (total necrosis); finally, 4, death of the entire bone, with perhaps some of the enveloping soft parts.

The first-named results were observed in three dogs, the examinations having been made on the 53d, 67th, and 73d days after the injury. The author also adds, as an interesting fact, that where necrosis was observed in one of the principal bones of the limb, it was not uncommon to find that the adjacent bone was affected with ostitis. The various stages of the inflammatory process in a bone were found to follow each other in the following order: Swelling and thickening of the periosteum; deposit of bone substance on the outer surface of the cortex; formation of bone in the medullary cavity; rarefaction of the tissue of the old compact tissue (enlargement of the Haversian canals, and with or without implications of the lacunae), so that it looked precisely like the new bony matter; thickening of the outermost layers of the periosteal deposits, by which a certain sort of new bony cortex was formed; finally, there was an apparent compression of the inner bony structures by connective tissue, so that in this way there was a new central cavity partly filled with fibrous tissue.

In the cases in which the second grade of the process was observed, it was about the holes that had been bored. In the remainder of the bone there was ostitis. The sequestrum was not fully loose, the examination being made at times ranging from the 30th to the 57th day. The sequestrum was either tubular, or at any rate curved. There was in this case also a deposit of new bone beneath the periosteum, the direction of the new bony fibres being vertical to the surface of the bone. The thickness of the deposit was greatest over the centre of the bone. The separation of the sequestrum was caused by the development of granulations in the interior of the old compact substance, while its remaining portion, together with the new deposit, formed the involucrum. In the third grade, where the entire thickness of the bony substance was destroyed, the sequestrum had a smooth surface, like a macerated bone. A point clearly shown in this class of cases was, that, wherever the outer surface of the sequestrum was smooth, there was a corresponding opening in the bony capsule. In the two cases of total necrosis, the involucrum consisted of two parts, the support of the limb being maintained by the fibula. This fact is said to agree with the experiences of Scarpa, Sédillot, and others, that, where the entire thickness of the compact substance takes place, there is no regeneration of bone tissue. It is to be explained by the fact that in these cases the periosteum is separated from the bone, which sets up suppuration, and thus bone formation is prevented. In total necrosis the continuity of the bony involucrum is endangered; in penetrating necrosis a continuous involucrum remains. The early or late removal of the sequestrum appeared to have no influence on the formation of bone. In applying these results to the question of operative surgery in children and adults, the author believes that much the same consequences may be expected. In children, where there is total necrosis of a portion of the bone, if there is bony union, shortening may be expected; but he thinks that after the twenty-fifth year the cases are very rare in which bony substitution occurs after total necrosis.

Of the fourth class, where death of the entire bone took place, the animals all died at times between the

end of the first day and of the first week. There was no reaction in any of them.—*Langenbeck's Archiv*, XX., 2, 1876.

**PSORIASIS OF THE MUCOUS MEMBRANE OF THE TONGUE AND MOUTH.**—The following are the main conclusions given by Dr. Nedopil, of Vienna, as the results of his investigations on this subject. Psoriasis of the mucous membrane of the mouth is caused by a chronic inflammatory process, which has its seat in the mucous membrane proper. The result of this chronic irritative process is a new formation of young, indifferent cells. Of these cells, those situated nearest the epithelial layer are transformed into true epithelium; in this way we may explain the abnormal and enormous deposit of epithelium and its rapid regeneration. The epithelial layer itself plays a passive part; it does not participate in the regeneration of epithelium. This is also true in the healthy tongue. The remainder of the newly-formed indifferent cells are in part transformed into contractile cicatricial tissue, in part persist as round cells, and may supplant the rest of the mucous tissue. These indifferent cells may take on an epithelial character before they arrive at their destined position; carcinoma is then developed out of them.

Bilroth, in a note to Dr. N.'s paper, while expressing the greatest confidence in the accuracy of the author's work, hesitates to accept his conclusions, and still maintains the old notion that epithelium only is derived from epithelium, and never from connective-tissue elements. As to the treatment of the disease, the author is opposed to the use of nitrate of silver, as it promotes the infiltration of carcinoma. Smoking should also be avoided and food that is either very hot or very cold. If an indurated or spreading ulcer forms out of an excoriation, or forms a fissure or psoriasis, the probability that the growth is carcinomatous is so strong that excision should immediately be undertaken, though it may have to be repeated many times.—*Langenbeck's Archiv*, XX., 2, 1876.

**LEUKEMIC TUMORS OF THE SKIN AND INTESTINES.**—Biesiadecki held an autopsy in a case of leukaemia, in which, besides the ordinary manifestations of the disease, there were numerous tumors of the corium, that had developed slowly on the forehead, the face, the breast, and the extremities. They consisted of slightly projecting nodules, varying in size from a lentil to a bean, and possessed all the characters of leukemic tumors, *i. e.*, the greater part of each tumor was made up of round cells resembling the largest white blood-corpuscles. Neither the spleen nor the lymphatic glands, although greatly swollen, presented changes that could be held to indicate an increased new formation of white blood-corpuscles within their tissues. The tissues proper of the spleen, liver, and kidneys were not only not hypertrophied, but were even atrophied. The white blood-corpuscles were altered, in consequence of an alteration in their protoplasm, and were deposited in these organs and parts of organs in which the pigmented cells are usually collected. The lymphatic glands only began to swell after the blood was already altered, and leukemic tumors had already been formed in the skin. These facts have led Biesiadecki to adopt the view that the swelling of the spleen and the lymphatic glands, and the changes in other organs, in leukaemia, are secondary lesions, while the disease of the blood is the primary lesion; that leukaemia is a parenchymatous disease of the blood, in which the white blood corpuscles are produced in normal quantity; but a metamorphosis of them takes place which prevents them

from changing into colored blood-corpuscles. In the Museum at Cracow, Biesiadecki found a preparation, evidently taken from an individual who had died of leukaemia, in which there were tumors in the mucous membrane of the intestinal canal analogous to the tumors of the skin in the above case.

Ponfick describes a case of splenic and glandular leukaemia, in which the origin of the disease could be referred with much probability to an injury of the spleen. That organ presented the remains of a peri-splenic process, the consequence of a kick of a horse that the patient had received one and a half to two years before his death. The spleen also presented fresh hyperplasia, such as is met with in leukaemia; but it was slight in degree. The disease was far more advanced in the medulla of the ribs, the sternum, and the bones of the thighs and legs, so that the organ in which the affection had presumably started was affected to a relatively slight degree.—*Berliner klin. Wochenschrift*, 20. November, 1876.

ON THE VALUE OF SALICYLIC ACID IN DISEASE.—In the wards of Prof. Wunderlich, in Leipsic, salicylic acid was administered in nearly 200 cases during the years 1875 and 1876. From careful study of its action in this large number of cases Dr. Bälz, formerly first assistant at the Medical Clinic, has deduced the following conclusions: salicylic acid deserves, as a rule, the preference over all other antipyretics, but it fails in certain cases, in which other remedies produce valuable results. Cold water and quinine still retain possession of their therapeutic domain, in which the new remedy cannot rival them; in other words, salicylic acid is not a panacea, but a polyacea, and Kolbe is entitled to great credit for his pressing recommendation of the new remedy as an antipyretic. Apart from its antipyretic action, it increases the excretions from the skin and the kidneys, and may, in consequence of this power, prove useful in the treatment of some cases of dropsy. The unpleasant nervous symptoms, such as tinnitus aurium, deafness, delirium, and mania, which sometimes supervene during its employment, usually disappear spontaneously, and are not dangerous.—*Archiv der Heilkunde*, I, 1877.

MEDICINAL PROPERTIES OF THE *ENOTHERA BIENNIS*.—Dr. N. S. Davis, of Chicago, recommends the use of this plant as a mild but efficient sedative in nervous affections, especially where the pneumogastric is involved, since it is useful in respiratory or gastric trouble, where there is a morbid sensitiveness in the laryngeal, pulmonary, or gastric branches of that nerve. This plant, generally known as the evening primrose, is common in the Middle and Northern States. It may be used in the form of the infusion or fluid extract. One or two teaspoonfuls of the former may be given to adults; of the latter twenty or thirty minims may be repeated every three, four, or six hours.—*American Practitioner*, Jan., 1877.

INTUSSUSCEPTION OF THE TRACHEA.—Dr. Lang, of Oehlingen, reports the following interesting case: a man, about twenty-eight years of age, slipped while climbing into a plum tree, and fell, but his feet catching in the branches, he remained hanging head downwards. He made violent efforts to raise his body so as to grasp the branch with his hands, but was unable to do so, and remained in his uncomfortable position for an hour before help came. Immediately after the accident dyspnoea set in, and increased from day to day. It was especially severe, and even bordered on suffocation when the patient let his head fall forward; when he held his head erect with the chin elevated

the symptoms were relieved, and his condition was bearable. He wore a stiff, high stock, in order to keep his head in this position. Many physicians were consulted by him, but none could discover the cause of the dyspnoea. Percussion and auscultation revealed nothing abnormal. Ten weeks after the accident the patient committed suicide. The autopsy revealed great enlargement of the space between the second and third tracheal rings, the stretched and elongated membrane being at the same time relaxed. When the head was flexed on the breast, the lower part of the trachea telescoped the upper part, the third tracheal ring being forced inside the second, and in this way the suffocative attacks were produced.—*Memorabilien*, 11, 1876.

THE EXCRETION OF CREATININ IN DIABETES MELLITUS AND INSIPIDUS.—Writers on this subject have usually agreed that the amount of creatinin excreted in saccharine urine is much less than in normal urine; in some cases none at all, or only slight traces of it being found. This seems strange, for two reasons: first, because diabetic patients are so generally confined to animal diet, and consequently take more creatin into the system than in a state of health; and, second, because examinations of the muscles, after death from diabetes, have shown that the amount of creatin contained in them is rather increased than diminished. Prof. Senator, of Berlin, in view of these facts, came to the conclusion that the failure to find creatinin in the usual quantity in the urine of diabetes, was due to imperfections in the method of seeking for it; and, after careful consideration and experiments, he adopted the following plan, which he has now employed, with satisfaction to himself, for several years: He takes one fifth of the whole quantity of urine passed by the patient in twenty-four hours, leaves it till it ceases fermenting, and then evaporates it rapidly down to 300 c.c.m., which is about equal to one-fifth of the quantity of urine passed in twenty-four hours in a state of health. During the evaporation an acid reaction of the fluid must be maintained—if necessary, by the addition of acids—as the change of creatinin into creatin is favored by an alkaline reaction. When this previous preparation is completed, the urine is to be tested in the usual way with chloride of zinc. Prof. Senator gives the results of nineteen examinations (ten cases) made in this way, which demonstrate that the amount of creatinin contained in the urine of diabetes mellitus is subject to great variations, being sometimes less than the lowest physiological quantity, and sometimes more than the highest. Consequently, neither an increase nor a diminution of the creatinin is characteristic of diabetes mellitus. In diabetes insipidus the excretion of creatinin is never so small in quantity as in some cases of diabetes mellitus. As the process of obtaining it is the same in both diseases, with the exception of the destruction of the sugar by fermentation, and as this fermentation has, according to Winogradoff, no influence on the creatinin, it is probable that, in many cases of diabetes mellitus, peculiar conditions exist, which lessen the excretion of creatinin or interfere with its separation from the urine. Prof. Senator examined the urine of five cases of diabetes insipidus eleven times for creatinin, and found that the average quantity (0.78 grm. in twenty-four hours) was very near the normal average (0.8-1 grm.). The average proportion of creatinin to urea in these cases was 1:65; in the cases of diabetes mellitus the proportion varied very greatly; the average normal proportion is 1:50.—*Archiv für pathol. Anat. und Physiol.*, LXVIII., 3.

## ASYLUM ABUSES AND THE TESTIMONIAL CAPACITY OF THE INSANE.

THE case of alleged cruelty towards a recent inmate of the Bloomingdale Asylum, which, at the time of its being made public, created such a sensation, has been examined into by Dr. John Ordronaux, State Commissioner of Lunacy, who has published his opinion upon the same. It will be recollected that Mrs. Jane Norton was admitted to the asylum in question on the 22d day of January, 1874, suffering from puerperal insanity, accompanied by a fixed delusion affecting her memory of faces and persons, and with the additional delusion that to partake of food would jeopardize the lives of her children. The latter condition necessitated artificial feeding. About a year after her removal from the asylum she complained to her husband of injuries inflicted upon her while there, and particularly of one done to her throat "while being fed by her attendants, forcibly and against her will." An examination of her throat revealed gross disfigurement, which was mainly due to adhesions between the right lateral margin of the velum palati and the uvula, and which were plainly traceable to previous extensive laceration. The husband accordingly instituted proceedings before the State Commissioner in Lunacy against the Society of the New York Hospital as the responsible agents of the alleged tort.

Although the statute creating the office of State Commissioner in Lunacy was designed to provide immediate remedies for persons in the actual custody of asylums only, it is a matter of congratulation that the form of complaint was such as to give the Commissioner power to adjudicate in this case. The plaintiff brought the action, not for the purpose of recovering damages or of securing revenge, but merely to have it "inquired into whether the wrongs alleged to have been committed upon his wife are part of a system of erroneous supervision now in force at the Bloomingdale Asylum."

The opinion rendered, as the result of a very careful and impartial hearing of the case, is not only of value in a legal sense, but the arguments upon which it is founded have a very important bearing upon the value of testimonial evidence of persons who are or who have been insane.

It is, perhaps, unnecessary to say that the defendants denied any cause for action. Responding to the charges, however, they admitted that Mrs. Norton was a patient in the asylum; that it was necessary to feed her by force; that the person charged with that office was an attendant by the name of Jane Eaton; that said person was skilful, trustworthy, and experienced; and that the injury to the throat was accidental, and consequent upon the resistance offered by the patient. There were other items in the complaint and answer which, comparatively speaking, are of small importance, and upon which it is not necessary to dwell here.

As the testimony of the husband of Mrs. Norton was based upon hearsay, it possessed no legal value, and the onus of proof rested necessarily upon Mrs. Norton herself. It is in the discussion of points referring to her ability to testify, and to the relative value of such testimony when offered, that the case derives its greatest interest. The whole argument rested upon the establishment of the fact whether the witness, conceding her to have labored under mental delusion at some previous period, was at the time of giving her testimony of sound mind; and if so, whether her recollection of circumstances occurring during her insanity could be relied on.

Evidently desiring to establish a precedent in this case, and wishing to give it for that purpose the widest latitude for testimony, Dr. Ordronaux thought that the most equitable way was "to allow her to testify in her own behalf, without previous examination, leaving that testimony to stand or to fall as a test of her mental competency, according as it squared with itself and was corroborative of facts otherwise circumstantially established." This novel method of investigation leaves nothing to be desired as to impartiality, and admits of no question as to the legitimacy of the conclusions founded upon facts thus ascertained.

Aside from this, the precedent is of the utmost importance in establishing a certain right on the part of any lunatic to testify in his own behalf, and in effectually combating any idea of unfairness towards him which may be entertained by the community at large. Mrs. Norton was accordingly allowed to testify. The force of her testimony depended naturally upon her power to observe facts correctly during her period of insanity, and recollect them afterwards. Viewed from a strictly legal stand-point, the possibility of either conditions, in the absence of objective and corroborative proof, would not be entertained; but Dr. Ordronaux was willing to go beyond these rulings for obvious reasons. It will not be a matter of surprise to

learn that the investigation did not result in establishing any new points of testamentary capacity in favor of one who at one time had been a lunatic.

Although it was proven that she had a retentive memory, she was unable to recollect some of the most important occurrences during the period of her insanity, many of them associated with bodily pain; that she could not recollect the manner in which she was fed; and that she so far lost all memory of her most intimate friends, that she repeatedly and constantly mistook entire strangers for them, and *vice versa*. In a word, during all that period, with a few unimportant exceptions accidentally corroborated by others, she was ruled by subjective sensations rather than by objective manifestations. Consequently, her testimony was thoroughly untrustworthy.

So far as a single case goes, this proves a great deal. The conclusions reached can hardly be questioned, founded as they are upon the careful investigations of a gentleman whose reputation as an expert in such cases is so deservedly and universally acknowledged. But, notwithstanding the result in this instance, it cannot militate against the general principle which Dr. Ordronaux has sought to establish, of allowing every lunatic similarly situated to offer personal testimony. Even if such a course is pursued upon merest presumption that such testimony may be of value, it is eminently justifiable as a happy mean to reconcile scientific fact with public prejudices.

While we may be willing to dismiss any charge of cruelty, either in intention or in fact, on the part of the managers of the Asylum, we must not lose sight of the elements in this case which refer to the responsibilities of the immediate attendants of the insane, and through them of the principals. In the absence of any testimony to the contrary, it is clearly proven that the injury to Mrs. Norton's throat was the result on her part of resistance to the necessary force to be used in feeding her; but, as Dr. Ordronaux very justly remarks, "the fact of such an injury, coupled with the want of knowledge of its existence by the physicians in charge of the Institution until a year after her removal, are incidents of asylum life which demand some official notice on my part." There is no reason why this should be so, unless as the result of culpable lack of skill or diligence, or both, on the part of the attendant. It is no excuse for the nurse that an insane patient makes no complaint. In the exercise of her functions as the constant and responsible attendant upon the sufferer, it was her duty to be cognizant of the slightest change in her condition, and to report it to the attending physician without delay. If such a course had been pursued, a monstrous public scandal might have been prevented.

Placing the most charitable construction upon this neglect of an obvious duty, we are reminded of the great difficulty in obtaining competent and reliable attendants in our asylums. Under the present system

of asylum management there does not seem to be much hope for a change in this respect, and the best that can be done is to supplement such services with greater watchfulness on the part of the physicians; or, as Dr. Ordronaux suggests, a distinct and authoritative supervision of the attendants by an officer appointed for the purpose.

There is another element in the question of actual responsibility of the attendants upon the insane, and that refers to an unwarrantable exercise of discretionary powers. Nurses who have held a given position for years are apt to presume too much upon their own judgment in regard to the relative value of new symptoms, and to report only such changes as they themselves may think sufficiently worthy of the attention of their superiors. We are happy to see that Dr. Ordronaux so fully appreciates the necessity of remedying this abuse of trust that he has officially recommended that the attendants make minute and daily reports of all patients under their charge, and that such reports be suitably transcribed in the case-books.

Referring to the case as a whole in its sensational relations to the public, we are glad that it has been so thoroughly investigated. The charges of cruelty which were made, were, as we expected, without foundation. Those who were willing to wait for the hearing of the case before passing judgment, were certainly on the safe side. In the light of an assurance to the public that cases of the sort will always be investigated, that any existing errors of management either as those of omission or of commission will be promptly corrected, it is well that the examination was made necessary. Far from supposing the management of the Bloomingdale Asylum to be derelict in its duties to its patients, we find it anxious for any suggestions for improvement, and willing to co-operate with every effort of the most radical and extreme reformer.

So marked has been this disposition, and so desirous has been the board to anticipate any necessity of change, that the Commissioner merely announces his conclusions in the shape of suggestions instead of giving them the usual force of legal commands.

**ANTISEPTIC OVARIOTOMY.**—Mr. Robert Barnes, of London, in reference to the question of priority regarding anti-septic ovariectomy, says that he performed "ovariectomy anti-septically, at St. George's Hospital, London, on the 31 of April last, and that previous to that time a successful case had been reported to him by the operator, Mr. John Couper." He says: "Whether this plan will contribute materially to lessen the mortality attending ovariectomy is still to be decided. At any rate, high success has at present been achieved with it. In hospitals and where there is suspicion of infecting agency it may be judicious to resort to it."

**SPIRITUALISM AND INSANITY.**—Dr. Carpenter, of London, asserts that investigations as to the nature and causation of what are alleged to be spiritualistic phenomena tend to mental unsoundness. He also declares that those who engage in this inquiry are on the road to insanity.

## Reports of Societies.

### NEW YORK MEDICAL JOURNAL ASSOCIATION.

*Stated Meeting, January 5, 1877.*

DR. CHARLES M. ALLIN, PRESIDENT, IN THE CHAIR.

#### REPORT ON SYPHILIS.

DR. R. W. TAYLOR made the annual report upon the above subject, and brought out, for the benefit of the general practitioner, salient points in the progress of the disease, rather than an elaborate dissertation suited to the demands of the specialists.

#### SYPHILIS AS A QUALIFYING ELEMENT IN THE REPAIR OF WOUNDS.

Reference was made, under that head, to reports of cases in which the affection had shown its unfavorable influence upon the process of repair; and the conclusion seemed to be that, in varying degrees, it was deleterious to the best interest of traumatism in general.

#### REINFECTION WITH CONSTITUTIONAL SYPHILIS.

It was regarded as important to determine whether reinfection was possible, for if established, it showed distinctly that one infection may run out; in other words, that the disease was curable. It was believed that a tolerable array of evidence existed in support of the doctrine that reinfection might occur. To a diagnosis of reinfection it was maintained that a general rash and adenitis were necessary.

#### MERCURY IN THE MILK OF NURSING WOMEN.

Reference was made to the observations of Klink, who held, contrary to the opinion expressed by Köhler, that mercury was present in the milk of nursing women under treatment for syphilis by the use of that drug, and that congenital syphilis might in that manner be cured. Klink was of the opinion that the reason why mercury had not been found by other observers was because of the insufficient quantity of milk obtained for examination.

#### COMMUNICATION OF SYPHILIS BY THE MILK.

In order to determine whether milk could communicate syphilis, Voss had obtained it from the breast of a syphilitic woman by expression, and injected three prostitutes by means of a hypodermic syringe. In one case syphilis followed, as proven by the development of a general rash and adenitis. He claimed, therefore, that the disease could be conveyed through the milk. Dr. Taylor criticised such conclusion on the ground that a single case did not prove the claim, especially as no evidence was given that there were not syphilitic lesions present upon the genitals and other parts of the body. Before such a case could be accepted it must be thoroughly positive that there was no point at which the syphilitic virus could enter save that where the milk was introduced.

#### SYPHILITIC RHEUMATISM.

From the report of Vassier it seemed that syphilitic rheumatism occurred more frequently in France than might be inferred from the writings of other authors. It was claimed by the same writer that in China and Japan it almost invariably occurred in the secondary period, and in a form which could be distinguished from true and hemorrhagic rheumatism, and yielded readily to specific treatment. It was believed by the reader, however, that the greatest care should be ex-

ercised in separating the cases of so-called syphilitic rheumatism from cases of rheumatism occurring in syphilitic persons. Voisin had also maintained that arthropathies occurred in all stages of syphilis, and were not, as perhaps more generally believed, confined to the tertiary stage.

#### SYPHILITIC PHTHISIS.

From the evidence which had been furnished it was believed that syphilis was a possible cause of phthisis, and, according to Fournier, it produced its effects in two ways: 1, by the development of syphilitic lesions in the lungs (gummata, etc.); 2, in the same manner as any cachexia does. It was remarked, however, that care should be exercised lest phthisis, occurring in persons suffering from syphilis, be regarded as syphilitic phthisis.

#### SYPHILITIC LESIONS OF THE RECTUM.

According to Barduzzi, stricture of the rectum might be due to the following causes: simple ulcer, soft venereal ulcer, lesions of secondary and tertiary syphilis, and cancer. Dr. Taylor, from observations made by others and from his own, was inclined to the opinion that there was some tendency to hyperplasia of connective tissue in the rectum in syphilitic persons. It was unattended, however, by pathognomonic symptoms, and the same condition of affairs might occur in persons who were not syphilitic. Dr. Taylor was prepared to admit that gummata and late tertiary lesions might produce stricture of the rectum, although he had never been able to diagnose such cases. Fournier had cited such instances, but at the same time had regarded them as very rare. Again, it was believed to be important to always bear in mind the question: was it a case of stricture of the rectum dependent upon syphilis, or was it simply a stricture of the rectum occurring in an individual suffering from syphilis, but developed independent of the specific disease?

#### TREATMENT OF SYPHILIS.

Reference was made to the studies of Guillaumet concerning the local use of *bi-sulphuret of carbon*, which acts as an irritant a refrigerant, and an anæsthetic; but in spite of the irritation produced, granulations rarely became sufficiently exuberant to require destruction. Its odor could be corrected by the addition of essence of bitter almonds or of mint, and there was no danger of accident from its prolonged inspiration. Combined with balsam of Peru in the proportion of one part to thirty of the balsam, it seemed specially beneficial, and not unpleasant. Combined with tincture of iodine it was rendered more efficacious and its activity augmented. The following formula was used:

℞ Carbon bi-sulphur..... ʒ ij.  
Tr. iodini..... ʒ iv.  
Ess. menth. virid..... gtt. xvi.  
M.

The solution was said to be inodorous. It should be applied with a brush or charpie, being careful to avoid a flame, slightly dust the surface with bismuth, cover with charpie and a bandage. The remedy had seemed to succeed in cases in which iodoform had failed. One application daily was usually sufficient. Pick, of Prague, had given a convenient formula for the use of iodoform. It consisted of iodoform three, alcohol ten, and glycerine thirty parts.

Dr. McMaster, of New York, had recommended the use of a piece of wood covered with flannel and smeared with mercurial ointment, in the treatment of syphilitic stricture of the rectum. The plug of wood

was to be worn constantly and retained in position by means of a perineal band. No inconvenience had been complained of after the first twenty-four hours, and during that time only a slight discomfort had been experienced.

Regimband was of the opinion that the sulphur waters of Luchon, in France, were not of much benefit in the treatment of syphilis unless there was a coincident administration of mercury. He believed, however, that larger quantities of mercury could be given without producing salivation and gastric disturbance, when the waters were taken at the same time.

Sigmund had employed the bi-cyanuret of mercury hypodermically in the treatment of syphilis, but had reached the conclusion that it was not a remedy of very great value, was less efficacious than corrosive sublimate, which he regarded as less valuable than the mercurial ointment used by inunction. Sigmund preferred calomel injections to all other methods. Kroworzynski believed the bi-cyanide to be more suitable than the bi-chloride of mercury for subcutaneous administration, as it did not cause such severe pain, created only slight induration of the tissues, gave rise to neither inflammation nor abscess, and did not produce pyralism or stomatitis. The size of the doses used by both observers was about the same, and consisted of one-tenth of a grain of the bi-cyanide to twelve drops of distilled water. The number of injections in Sigmund's cases ranged from twelve to twenty-nine.

Bumberger proposed an alluminate of mercury, as being more readily assimilated and causing less reaction.

Dr. Taylor's report gave evidence of having been drawn up in an honest and careful manner. Remarks, mainly in way of detailing the histories of obscure cases, were made by several gentlemen, and the Association adjourned.

## NEW YORK ACADEMY OF MEDICINE.

SECTION ON THEORY AND PRACTICE OF MEDICINE.

DR. GOUVERNEUR M. SMITH, CHAIRMAN.

*Stated Meeting, January 16, 1877.*

### THE DISEASES OF THE CENTENNIAL EXPOSITION.

THE above subject being before the Section, Dr. AUSTIN FLINT remarked that it was quite probable the discussion would have chief reference to the etiology of *typhoid fever*: The following points were submitted for consideration. First, it was desirable, as far as possible, to determine the number of cases of typhoid fever occurring among those who had recently visited the Centennial Exhibition, as affording evidence that the disease was due to the reception of the morbid agent while there. In determining that point, it was important to take into account the period of time which elapsed, after visiting the Exhibition at Philadelphia, before the disease was developed. Such period must conform to that ordinarily elapsing, where a person has been exposed to the poison, before the disease was developed—namely, about two weeks. The fact, that three or four weeks had elapsed before the development of the disease, would rather exclude the cases from the list of those who had contracted it at Philadelphia.

Assuming that the disease involved a special cause, it was possible that facts might be gathered relating to certain important questions concerning the etiology of typhoid fever, which were at present *sub judice*.

Did the special cause of typhoid fever always involve the presence of a morbid virus? The view held by many of the profession, notably by Liebermeister, in Ziessens's *Cyclopaedia*, was, that a morbid product was essential in all cases; that the product was formed in the alimentary canal; that it escaped from the body with the dejections; that in the condition in which it escaped it was inadequate to produce the disease; but that after leaving the body it underwent certain developments or changes, which rendered it competent to produce typhoid fever. The disease was not, therefore, contagious, in the ordinary sense of the term, but was indirectly communicable in the manner to which reference had been made. Assuming that view to be correct, and assuming that the special cause of the disease was received at Philadelphia, there must have been dejections from typhoid patients there, furnishing such product, and circumstances for the changes or developments necessarily existing there at the same time. Were there any facts to be presented which had a bearing upon that question? On the other hand, was it a more probable view that the special cause of typhoid fever did not necessarily in all cases involve the presence of a morbid virus? Might not the special cause of the disease be produced without any such virus, under certain circumstances, and those circumstances relating to collections of human excrement?

Second, assuming that the special cause of the disease had been received by a certain proportion of those visiting the Exhibition, what had served as the medium for the introduction of such special cause into the body? Was it received by means of drinking-water, as it was altogether probable, that, in certain cases at least, it might be introduced into the body in that manner? For facts relating to pollution of the drinking-water by the introduction of sewage, reference was made to the *MEDICAL RECORD* for October 24th, 1876.

In connection with that question, it was also important to determine how far typhoid fever had prevailed in the city of Philadelphia—whether it had prevailed more extensively in those parts of the city supplied with water derived from the source in which the pollution was ascertained to exist, as compared with those districts, if there were any, which received water from other sources. It was regarded as desirable that some one in Philadelphia should now investigate and report the facts bearing upon the points of inquiry just suggested, whatever may have been the feeling of city pride regarding such inquiry while the Exhibition was in existence.

With regard to the pollution of drinking-water, it was to be considered that the quantity of organic matter present was not a guide to the existence or abundance of the special cause of typhoid fever. The special cause might be present with a small quantity of organic matter, and on the other hand a large quantity of organic matter might be present without embracing the special cause. In other words, it was the quality and not the quantity of the organic matter in the water which was capable of giving rise to the disease. Again, it was important to determine whether, among the persons who became affected with typhoid fever, deriving the cause at the Exhibition, there were cases in which drinking-water did not convey the poison into the system, because derived from sources in which contamination could not have occurred.

Drinking-water might be received into the system not as water, but as it was obtained in milk, beer, and a variety of beverages manufactured upon the ground. Another point of inquiry would relate to the influ-

nce of accessory causes, such as over-exercise, mental excitement, errors in diet, etc. It was, however, to be borne in mind that those causes were not competent in themselves to produce typhoid fever, but they might render the system susceptible to the influence of the special cause.

A discussion of the nature of the special cause of typhoid fever was not entered upon, but it was believed that the germ theory, the theory that the disease depended upon the presence of low organisms, either animal or vegetable, was the one which harmonized more closely with our knowledge than any other. It was believed to be the theory which had in its favor vastly more probabilities than any other; and facts could be more easily explained by reference to this theory than by reference to any other. Another point to be borne in mind, and one made by Liebermeister, was, that the special cause of typhoid fever might occasion disturbances of the alimentary canal, and more or less general disturbance, without giving rise to the disease itself. It seemed to be a well-recognized fact that a considerable proportion of visitors at Philadelphia, during the time of the Exhibition, suffered more or less from disturbances of the alimentary canal and general disturbance of the system. Then the question arose, were such disturbances due to the action of the special cause of typhoid fever without producing the disease itself, or were they due to accessory circumstances? Brief allusion was then made to six cases which had fallen under the doctor's observation, and which occurred after visiting the Exhibition, within the period corresponding to the period of incubation of typhoid fever. One case was characterized by repeated and profuse intestinal hemorrhages. One case terminated fatally after a few days of sickness, and without important complication. One patient was sixty years of age; diarrhoea and tympanitis were prominent symptoms, and a fatal termination ensued.

In all the cases the symptoms were such as to scarcely leave a doubt regarding the nature of the disease.

DR. O. WHITE referred to several cases of gastro-intestinal disturbance developed while visiting the Exhibition, but had not seen cases of typhoid fever. The cases of gastro-intestinal derangement had been characterized by profuse perspiration and great prostration in many instances, and in almost all there had been present spots of hyperæsthesia. For example, in one case the attack was preceded and accompanied by a severe burning, stinging pain upon the anterior surface of the thigh, just above the knee; in two cases the burning sensation was at the back of the neck; in another upon the left leg below the knee; in still another one of the toes felt as if scalded, and, soon after, an attack of vomiting and diarrhoea was developed. In the last case the scalding sensation disappeared from the toe and appeared upon the left index finger. The doctor had not recovered from his own attack, and was obliged to take quinine daily. While at the Exhibition he and his party were not guilty of errors in diet, and drank little or no water. Dr. White was of the opinion that the accessory circumstances were not sufficient to account for the gastro-intestinal disturbance from which he suffered.

DR. LEALE referred to a case which he regarded as one positively of typhoid fever, and which could be traced directly to the Centennial. The patient was seventeen years of age, and on the fifteenth day after the chill had the eruption of typhoid, diarrhoea, dry skin, pulse 130, and temperature 106° F. For more than a week subsequent to that date the temperature ranged from 103 to 106½° F. The case was severe and prolonged, but recovery finally took place.

In several cases, symptoms like those introducing typhoid fever had been present; but the use of fifteen grains of quinine daily for a few days had broken up the attack.

DR. LOOMIS had seen, since October 2, 1876, six cases of fever, which from their histories seemed to have their origin in a visit to the Centennial. All the cases had certain prominent symptoms, but differed somewhat in detail. He had not regarded any of them as cases of typhoid fever. In every instance the attack had been ushered in by a distinct chill. During the first few days there had been, without exception, marked remissions and distinct exacerbations; all had marked gastric disturbance at the commencement, followed or accompanied by diarrhoea, which in every case was of a brown watery character, and never assumed any of the characteristics of typhoid fever discharges; an eruption was present in all the cases, but it was not the typhoid eruption; as the cases progressed, the remissions became less marked, the exacerbations more distinct and prolonged, until finally the fever assumed all the characteristics of continued fever. The above was given as the history of all six cases. A peculiarity was, that the skin assumed, not a jaundiced hue, but a dark slate color, which seemed to be marked in all cases as they progressed. Hemorrhage from the bowels occurred in two cases late in the disease; in one it was quite profuse, in the other only slight. Pulmonary complication did not occur in any case. The severity of the illness differed; some were very sick; others only moderately so; one case terminated fatally. At autopsy intestinal ulcerations were found in all stages, from the slight enlargement of the intestinal glands on to destruction of the mucous membrane and invasion of the muscular coat beneath. In some places the ulcers had cicatrized. The patient died on the thirty-eighth day of the disease. There was pigment in some of the ulcers; the liver was pigmented and enlarged; the spleen was not so soft as in typhoid fever; the heart assumed very much the appearance presented in cases of death from typhoid fever. The intestinal ulcers differed in appearance from those of typhoid fever as the doctor had seen them. From the history, Dr. Loomis was led to regard them as cases of malarial fever assuming a typhoid type—perhaps might be called typho-malarial fever, or camp fever. Dr. Loomis had also seen a number of cases of gastro-intestinal disturbance, probably having their origin at the Centennial; but it had not been followed by marked febrile excitement. In one case the patient had twenty passages within twenty-four hours, and the only remedy which seemed to exercise any control over the diarrhoea was twenty grains of quinine.

The reasons for not regarding the cases as typhoid fever were, that the typical temperature was absent; they began with a chill; there was no characteristic typhoid eruption. There was tympanitis and intestinal disturbances; but those were symptoms which were present in other than typhoid fever. The cases differed from typhoid fever in their duration; for it was very rare for typhoid to run longer than twenty-eight days. If it did continue longer, it must depend upon complications or relapse. In all six cases the fever ran five or six weeks, and convalescence was protracted.

DR. FLINT asked Dr. Loomis whether malarial fever possessed the capability of becoming typho-malarial fever without the agency of the special cause of typhoid fever.

DR. LOOMIS replied that he did not regard typho-malarial fever as having any relation to typhoid fever, as far as cause was concerned. By typho-malarial

fever he understood a fever having a malarial element and an animal element, which he would call a septic element, due to an animal poison, which was not the specific poison of typhoid fever. In some cases the malarial element predominated; in others the typhoid, and the variations in the course of the disease corresponded, on the one hand, to the amount of malaria, and on the other to the amount of septic poison present, which was not the specific poison of typhoid fever.

DR. HADDEN—Does that fever reproduce itself?

DR. LOOMIS—I have not seen such instances.

DR. HADDEN—Has it not been considered that camp fever reproduces itself?

DR. LOOMIS—That was not our experience here during the war.

DR. HADDEN—My experience has been different.

DR. LOOMIS—I was not aware that camp fever was regarded as one having a contagious element, unless it be typhus, which has been called by that name.

DR. HADDEN remarked that the cases he had seen in camp were not pure typhus, nor were they typhoid fever, and yet the disease had reproduced itself.

DR. LOOMIS remarked that cases of typho-malarial fever varied in type according as the malarial element or crowding, as occurred in camp, was the stronger. In the latter instance almost all the characteristics of typhus, and but few of typhoid, fever were present. If there was any fever which the typho-malarial resembled more than another, it was the relapsing.

DR. HADDEN remarked that he had seen a number of cases of gastro-intestinal disturbance, and had been able to trace most of them to exhaustion, promiscuous eating, and other indiscretions while visiting the Centennial. Rest, regulation of diet, without much medication, had restored them to health.

DR. WARD had seen several cases similar to those mentioned by Dr. White, and all were relieved by quinine. They resembled cases seen in the swamps of Louisiana during the war. He had had one patient who was upon the Centennial ground a single day, took to her bed twenty-one days after, and presented well-marked symptoms of typhoid fever, such as chilly sensations, not distinct chills, at the commencement, diarrhea, bloody stools, high temperature, with distinct evening elevation, debrium, and characteristic typhoid eruption. The case terminated in recovery.

DR. HADDEN inquired of Dr. Loomis, if, after having typho-malarial fever, there was an immunity from a second attack.

DR. LOOMIS was of the opinion that the first attack did not afford protection, any more than was seen in any other form of malarial fever.

Cases, not differing materially from those cited, were mentioned by several gentlemen present.

THE CHAIRMAN remarked, that it would seem, from the reports made, that visitors at the Centennial had been exposed to poisons capable of giving rise to a variety of diseases. For manifestations of mild malarial poisoning, of the influence of the specific cause of typhoid fever, and of the typho-malarial poison, had been noted.

It was remarked, by one of the gentlemen present, that the apparent presence of different poisons might be due to a difference of opinion regarding the exact nature of the disease which had been developed.

NEW YORK PATHOLOGICAL SOCIETY.—The committee on microscopy for the ensuing year is composed of Drs. T. E. Satterthwaite, J. A. McCreery, and Geo. F. Shrady.

## Correspondence.

### RETRO-PHARYNGEAL ABSCESS AS A SEQUEL OF DIPHThERIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Noticing an article in the RECORD of November 18th, copied from the *Jahrbuch für Kinderheilkunde* upon the above subject, and its rare occurrence in diphtheria, I take the liberty of enclosing an extract from my case-book, which may prove of sufficient interest to warrant publication.

Eddie N—, æt. 5, of good parentage and robust constitution, convalescing from an attack of diphtheria (which was developed suddenly the day after the commencement of the desquamative stage of scarlatina anginosa), had been troubled by a tumefaction at the back of the neck, which resisted all ordinary measures of counter-irritation, etc.

December 26th.—Was called suddenly, as great uneasiness, pain, etc., was occasioned by swelling. Upon examination great swelling and tumefaction under left ear was detected. Diagnosed a retro-pharyngeal abscess, although no fluctuation evident. Ordered flax seed poultices and exhibited gr. ss. quinia sulphas every four (4) hours.

December 27th and 28th.—No embarrassment of respiration, but a steady increase of swelling.

December 29th.—Found him suffering intensely with great increase in tumefaction. Face slightly swollen. Can only take fluids by mouth; jaws stiff. Upon examination of the throat I found nothing that would warrant lancing. With a hypodermic syringe I punctured abscess behind ear, and at the depth of one and a half inches obtained a slight amount of pus. I made another puncture half an inch below lob of ear, and at the depth of one and one-eighth inches in a *direct* line, aspirated over 5 ss. of thick, laudable pus, with immediate relief of distressing symptoms. Ordered a continuation of poultices, and exhibited quinia sulphas gr. ss. every two (2) hours.

December 30th.—Better, but an increase of swelling.

December 31st.—More uneasy. Some tumefaction of cellular tissue of face. Abscess increasing. Pain paroxysmal and intense. Tendency to point over seat of puncture. Ordered poultices, with laudanum and quinia as before.

January 1st.—Weaker. Abscess enormously distended and points, although matter deep-seated. Desired to lance, but at solicitation of parents delayed until next visit.

January 2d.—Opened spontaneously at about midnight, discharging *freely*.

The patient, upon the syrup of iron and quinia made a good recovery, and at present is nearly well.

J. W. BROWN, M.D.

MONTVILLE, N. Y., January 13, 1877.

### DR. HOLDEN'S RESONATOR.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Since the article in your recent number, entitled "A Discovery in Physical Diagnosis," I have received so many letters of inquiry that I trust you will permit me to correct an unintentional error in describing the particular "resonator" I have used.

As stated, the instrument was of soft rubber,  $\frac{3}{8}$  of an inch in internal diameter, with end pieces  $\frac{1}{4}$  of an inch in diameter, of thin brass. Upon careful meas-

ment of a piece of the tubing, unstretched, I find but  $\frac{1}{2}$  an inch in diameter, the rubber  $\frac{1}{16}$  of an inch in thickness. The distant end-piece is  $1\frac{1}{4}$  inches in diameter and about  $\frac{1}{16}$  of an inch thick; but a point which is of vital importance is that the mouth-piece—while of the same external diameter—in order to stretch the tube and produce narrowing, is itself narrowed inside to  $\frac{5}{16}$  of an inch. This I now find essential to my results; but it was overlooked because the tube was a part of another instrument. The following are the exact dimensions of the tube used:

Material, soft rubber,  $\frac{1}{16}$  of an inch in thickness; external diameter,  $\frac{1}{2}$  an inch; length,  $17\frac{3}{4}$  inches.

Distal end-piece of thin brass and  $\frac{3}{4}$  of an inch in external diameter, and  $\frac{1}{16}$  of an inch in thickness, and  $\frac{1}{2}$  inches long.

Proximal end-piece (mouth-piece), of wood or metal, same external diameter, and same internal *at its extremities*, but narrowed in its middle to  $\frac{5}{16}$  of an inch and  $1\frac{1}{8}$  inches long. The mouth-piece of a trumpet would doubtless be better.

By giving a prominence to the above statement, equal to that with which the article in question was favored, you will, I doubt not, oblige the many subscribers who have written concerning it.

Yours truly,

EDGAR HOLDEN.

HEATING THE STREET-CARS.—The investigations into this subject by the Committee of the Board of Aldermen seem to prove a great many contrary things. One party testifies that heat is detrimental to the health of the passengers, and another that cold produces the great majority of the cases of pneumonia, diphtheria, bronchitis, and the like. But there is a happy mean between a closely packed oven and a travelling ice-box. A step has been taken in the right direction, by the recommendation that the cars shall be properly ventilated, be plentifully supplied with clean straw, and have the front doors permanently closed during cold weather.

A NEW HEALTH BILL.—At every session of the Legislature there must of necessity be some radical measures for reform in city government proposed. Next to the affairs of the Police Department those of the Health Board receive the most attention from tinkering law-makers. Within the last few days a bill has been introduced into the Assembly creating a new Board of Health for this city. Why such a measure should be considered necessary we are at a loss to determine, and the more so when we become acquainted with its absurd provisions. The latter comprise the

appointment of six commissioners to constitute the Board, three being members of the Police Board and three being physicians. The physicians are appointed by the Mayor, and are to serve for two, four, and six years respectively. One of these physicians is to be elected Sanitary Superintendent, at a salary of \$6,000 per annum, and all the others are to serve the State gratuitously. The places of the sanitary inspectors are to be taken by the police surgeons. As there is not the slightest chance of the passage of this bill, we merely mention its presentation as a matter of form and an item of news.

TRICHINOSIS.—Several cases of trichinosis disease have been reported in New Haven, Conn.

SIX MONTHS WITHOUT FOOD.—Another remarkable instance of life being sustained without food makes its appearance in the Pittsburgh (Pa.) *Telegraph*. The patient is a beautiful young lady, of course, with angelic eyes, fine plump limbs, and suffers from the dreadful affliction of having no board to pay, with a resignation in keeping with her saintly disposition. And, after all, what a pity it is she should be tortured thus, and that the most brilliant medical talent in the neighborhood is of no avail. How much longer she may live without food is a question which can only be decided by the degree of stupidity of such as may be willing to believe her story. At the last accounts she was 22 years of age, the picture of health, and weighed 150 pounds.

If the less she eats, the more she weighs, how little must she consume before she can weigh two hundred?

NEW YORK EAR DISPENSARY is in a flourishing condition, having afforded and during the past year to five hundred and seventy patients. It is now in its eighth year of existence. Dr. Samuel Sexton is Surgeon in Charge.

A NEW FEVER COT.—DR. G. W. KIBBEE, of this city, has devised a cot for the purpose of treating patients by cold water. It is constructed with two side-pieces, eight inches wide and six feet ten inches long, allowing room for head and foot boards, and leaving six feet six inches in the clear. To the upper edges of these side-pieces is fastened a strong open-work cotton blanket stuff, which permits the water that is poured over the sheet or bandage that encircles the trunk to pass readily through and fall upon a rubber cloth attached to the under edges of the side-pieces, and sloping towards the foot, so as to carry the water off into a receptacle. To the outer sides of the wide pieces, or rails, are screwed malleable iron castings that receive the ends of the legs which cross each other below, and are so bolted together as to be movable, allowing the bed to be closed up and set away when not in use. It is so constructed that it can be taken apart and closely packed for transportation.

Dr. K. writes: "This Fever Cot was invented in the summer of 1875, during a scourging epidemic of typhoid fever in the Willamette Valley, Oregon, to facilitate the use of tepid or cool water. For many years I had been in the habit of regulating the heat of fever patients with water, and found that the best effects were produced by pouring tepid or moderately cool water over the trunk through a folded sheet, or bandage, of several thicknesses. That method being inconvenient, on account of soiling the bedding, I at last reached the idea of this Fever Cot, which obviates the whole difficulty. Water, at any desired temperature, can be poured or otherwise used without wetting anything but those articles used about the patient. It is wholly unnecessary to descant

on the value of the *cooling process* in fevers, as the recent extensive use of water in the hospitals and private practice of Europe is well known through our medical journals and newspapers.

"The philosophy of Cold in all fevers is fast coming to light through the experiments by scientists on *fermentation*, it being found that the vitalized germs require a certain high range of temperature for such development and reproduction as render them dangerous or fatal to life in the higher forms of being. This Fever Cot is therefore offered to the attention of the medical profession, and the world at large, as the most feasible apparatus yet discovered for regulating the heat of fever patients, and keeping it at the normal standard, thus preventing all danger from infectious poisons, which, as has been proved by recent practice, can do no harm while the temperature of the blood is held at 98."

**NUMBER OF STUDENTS IN THE GERMAN UNIVERSITIES.**—In the summer session of 1876, the number of medical students entered in the German universities was as follows: Vienna, 789; Würzburg, 527; Leipzig, 378; Dorpat, 353; Munich, 347; Berlin, 260; Greifswald, 235; Gartz, 194; Zurich, 193; Tübingen, 179; Strasbourg, 178; Breslau, 165; Bern, 147; Erlangen, 141; Königsberg, 139; Freiburg, 128; Bonn, 127; Marbourg, 126; Göttingen, 112; Halle, 103; Heidelberg, 101; Giessen, 96; Jena, 82; Innsbruck, 81; Basel, 76; Kiel, 73; Rostock, 29—in all 5,372.

THE AMERICAN VETERINARY REVIEW is a new journal, devoted to the interests of veterinary medicine and surgery, and published under the auspices of the United States Veterinary Medical Association. A. Liautard, M.D.V.S., is editor, and A. Lockhart, M.R.C.V.S.L., is assistant editor. Both of these gentlemen are well known in the veterinary world, and bring to their work rare abilities and extensive experience. The first number of this periodical appeared this month, and contains the following papers, read at Philadelphia on the 13th Anniversary Meeting of the Association, viz.: History and Progress of Veterinary Medicine in the United States, by Prof. A. Liautard M.D.V.S.; Zymotic Diseases, by Prof. James Law, M.R.C.V.S.L.; Use of Stimulants in Diseases, by A. A. Holcombe, D.V.S.; on the Causes of Some Chronic Lameness of the Foot, by Theod. Very, V.S.; and the Report of a Case of Erysipelatous Cellulitis, by E. F. Thayer, M.D.V.S.; on Sanitary Measures, by Prof. J. McEachran, M.R.C.V.S.L. All of the articles are of first class merit, and if those in the succeeding numbers are equal to them in practical interest and strictly scientific value, the journal cannot fail to command not only a large patronage from veterinarians, but from the medical profession at large. We gladly welcome it to our exchange list.

**CARE OF CRIMINAL INSANE.**—At the recent Annual Meeting of the State Prison Association the following was adopted:

"Resolved, That a committee of five be appointed by the chair to investigate and report to this Association as to the condition and treatment of the insane in the various penitentiaries and prisons in this State and about this city."

The chairman appointed the following gentlemen to act as such committee: Charles H. Kitchel, Z. Styles Ely, Dr. Elisha Harris, James H. Titus, and Theodore H. Mead.

SMALL-POX is still prevalent in London.

THE LONDON PATHOLOGICAL SOCIETY numbers 582 members.

**COLOR BLINDNESS AND RAILWAY ACCIDENTS.**—There has been so much talk of late in regard to railroad accidents and color blindness of engineers, and signal men, that in France and England a previous ophthalmoscopic examination of the eyes of such persons is considered a necessary condition of their appointment.

**THE TURKISH ARMY.**—The health of the Turkish army is reported as good. The military hospitals at Nish are capable of containing 8,000 wounded; they are however little better than sheds, are badly drained and badly lighted. The balls from the Servian rifle are said to produce severe injuries, crashing through fascia, muscle, and bone, often splitting the long bone like wedges. In the majority of such cases repair is almost impossible, while amputation above the knee is nearly certain death.

**MILK INSPECTION.**—The Health Board has recently passed a resolution to the effect that the Board of Police detail two officers for the special service of inspection of milk under direction of the Sanitary Superintendent, and also that the Sanitary Inspectors perform such office in their respective districts. If the Health Board lactometer is to be depended upon as formerly, the inhabitants can be certain of obtaining what is facetiously styled by milk dealers a "Health Board" milk. It is to be presumed that there will be an active demand for Health Board lactometers. As the case now stands, the Inspectors can not determine by the lactometer whether milk is adulterated with water or with cream, and practically it does not seem to be of much importance so long as the specific gravity is at the regulation level.

**A NEW JOURNAL.**—Among our latest exchanges is the *Revue de Littérature Médicale*, a recent addition to the already large number of medical journals published in Paris. The greater part of the number before us is devoted to original articles—reports of societic finding apparently no room in it. One of the admirable features of the journal is a series of short notices of celebrated medical men of the past, accompanied by photographs. A less admirable feature is the reprinting of Rabelais' work, in a serial form, in the feuilleton. This looks like poverty of material.

**LACTO-PEPTINE WITH QUININE.**—Dr. C. W. Davis, of Indianola, Iowa, speaks very highly of the use of quinine and lacto-peptine. He has sent us an account of some cases in which the use of the compound has been strikingly beneficial. He concludes that "lacto-peptine strengthens and invigorates the digestive system, causing the quinine to be rapidly and thoroughly absorbed, thereby securing the full effect of its great tonic and curative powers—requiring not over half the quantity of quinine to gain the desired result."

**JOHNS HOPKINS HOSPITAL.**—Dr. J. S. Billings, of Washington, and Dr. E. M. Hunt, of Metuchen, N. J.—who were recently sent abroad by the trustees of the Johns Hopkins Hospital for the purpose of examining into and reporting upon matters of hospital construction—have returned. While visiting the different charitable institutions of Europe, they had ample opportunities for collecting information, which will be made available to the great Baltimore Hospital.

**REVACCINATION** in London is being urged by the authorities. The *Lancet* thinks that the belief that, because revaccination fails to take, protection is complete, is a dangerous error, and says that fully ninety per cent. of revaccinations will succeed if done from the arm or with a well-charged tube of moist lymph.

## Original Lectures.

### EXAMINATION FOR LIFE INSURANCE.

By WILLIAM DETMOLD, M.D.

EMERITUS PROFESSOR OF CLINICAL AND MILITARY SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK CITY.

(Photographically reported for the MEDICAL RECORD.)

#### LECTURE I.

GENTLEMEN:—The subject of "Examination for Life Insurance" is one of great importance, not only to the community at large, but to the medical profession. It is probably a low estimate, when I state that the life insurance companies in this country pay annually to medical men the sum of one hundred and fifty thousand dollars for examinations; and that amount, for the most part, is distributed in small sums among the younger members of the profession. The object of these lectures is to give some idea as to what constitutes the duty of the medical examiner.

Life insurance, or assurance, as it is now called, is the insurance of a certain sum of money that is to be paid at the death of the insurer. The institution of life insurance has, if memory serves me right, its earliest date during the reign of Queen Anne, of England; but it did not amount to anything at that time, and it is only within the present century that the business has assumed large proportions. The amount of insurance on life in England is now over five hundred millions of dollars, and in this country it probably exceeds that sum by considerable. Those persons who live on a salary, or wages, or on the receipts from their business, and whose income naturally will terminate with their lives, must, as a matter of course, have anxious desires to secure to their families a comfortable subsistence in case of their own death. Now, if a man were sure that he should live to the average duration of human life, he might save from his annual income sufficient to secure his family against distress; but the life of the individual is exceedingly uncertain. On the other hand, there is nothing more certain than the average duration of human life. What is very uncertain in the individual becomes almost a positive certainty when a multitude of lives are made the basis of calculation. There are few things subject to less fluctuation than the calculation of the average duration of human life when it is made with reference to a multitude of people. Death from old age is very rare—bearing the proportion of only about five and a half per centum of the whole number of deaths. The tables known as "The Carlisle Tables" have given us the most accurate calculations regarding the average duration of human life; and although rather complicated, the probable duration can be reached in the simplest manner as follows:

To the age taken add two-thirds of the difference between it and eighty, and you will have an almost unerring calculation of the average duration of human life. For example, let us take the age twenty; the difference between it and eighty is sixty; two thirds of the difference equals forty; and forty added to twenty equals sixty, or the average duration. Of course this calculation does not apply to the individual; and it cannot be said of any one of you who may be twenty years old that he will live to see sixty years. But for a thousand persons at the age of

twenty the calculation is correct, and will give an average duration of sixty years. Now, life insurance is based upon this calculation. The company fixes upon that annual premium which, at the end of forty years, assuming that the age of the applicant is twenty years, will enable it to pay the amount for which the applicant is insured. If, for example, one thousand persons, at the age of twenty years, insure their lives for two thousand dollars each—which amounts to two millions of dollars of insurance—promised to be paid at the end of forty years, the company divides that amount among the one thousand persons insured, so that with the accumulated interest it shall be able to pay the sum due at the expiration of forty years; of course, also providing for the expense of the business transaction. Suppose, however, that among these people—applicants for insurance—there are five hundred who are carrying within them the seed of early death; they have a phthisical diathesis, or any other which is likely to terminate life at an early date, then of course the calculation will not hold good, and the company will not be able to collect the amount necessary to meet the coming demand before it will be demanded. For that reason it is that every applicant for life insurance is subjected to a rigid medical examination. You will therefore easily comprehend that the corner-stone of the life insurance company is the medical examiner, and that upon him depends the safety of the company. He should not therefore acquiesce in taking any life risk which already contains the evidences of probable early death.

Medical examination should be made, as a matter of course, with judgment and discretion, but should be conducted with the special object in view for which they are made.

For example, you may be called upon, though I hope you never will, to make examinations for forced conscription, such as many were called to do during the late war in this country. In that case you may rest assured that all the men presenting themselves will exaggerate the slightest defect they may have, and simulate defects which they have not, in order to evade the service. In such an examination you have to guard against deceptions in a special direction, and have nothing to do with reference to the question of probable longevity. The question you have to answer is, Is it probable that he will be fit to serve for the term of enlistment? If he is able to serve as long as he is required, whether three months or three years, you will take him, without reference to the fact that some other members of his family have died early in life. On the other hand, if you are called upon to examine volunteers or substitutes, you have to deal with a class of men who wish to conceal their defects for the purpose of getting into the army or navy; but as soon as they are in, the concealed complaint shows itself; they are unfit for service, and will claim a pension. Again, you may be called upon to examine a person who is a malingeringer, who prefers to draw a weekly stipend from some benevolent society rather than go to work or to war; in such case you have only to judge whether the person is able to do his work, of whatever kind it may be. If he is a scribe, and is lame, he can do his work. If he is a letter-carrier, and can walk without trouble, he can perform his duties, even though he does have a somewhat lame shoulder. The examination for life insurance, however, is entirely different. The recruit may be rejected because he has lost a finger or thumb; but you must recollect that does not interfere with the probable duration of life in his case, and he may enjoy excellent health, although not fit for a recruit. In life insurance examination you are to judge

of the probabilities as to whether the man is likely to have the average duration of human life.

Now, in applying for life insurance, every applicant is anxious to pass a satisfactory examination. Here, again, it will be necessary for you to guard against the deception which may be practised by the applicant in concealing defects which, if exposed, might be objectionable. You may remember, however, that the examination for life insurance, which is most likely to fall to your lot to make, is not final. The final decision, whether the applicant is to be taken, is made at the principal office. There are physicians there who will examine the result of your examination, and you are only to give such facts and data as will enable them to arrive at a correct and final decision as to whether the risk upon a given life should be taken or rejected. Before I proceed any further I wish to impress upon you the fact that there is one requisite which is pre-eminently necessary in the young examiner. I insist upon that, because it is a quality which should guide you and every man in all his pursuits; I mean strict honesty. The young practitioner in small places is exposed to great temptations. Suppose, for instance, in a small town an influential citizen, such as the mayor or the parson, fears that his health is failing; he has his first premonition of trouble about his heart; he has palpitation; and he concludes that he had better make some extra provision for his family; in short, he wishes to insure his life. Such a man's good-will might be of great use to a young practitioner in a small town, and it is a very easy thing, and it is very tempting, to overlook a little murmur about the heart, and so secure the influence of the influential man, and with that the good-will of a number of respectable families. It is very tempting; but it is nothing more than downright robbery. You may be certain the company will find out the facts in the case, for the companies investigate very thoroughly before paying the insurance, and upon the least suspicion your future service will be dispensed with. I can tell you a case in point. A very respectable congregation, "all honorable men," discovered that the health of their clergyman was failing, and a council was held. Inasmuch as he had been a faithful servant in the pulpit, they concluded that it would be no more than right to provide for his family to a certain extent, and at once applied to a life insurance company for a policy. When the doctor made his examination and rejected the applicant, the whole body of men were highly incensed because of it; they were surprised that he should disapprove of "one of the best notions in the world," and were not able to understand why he should refuse his consent to such a good scheme. But the examiner had heard a distinct murmur about the heart, and the parson died within twelve months. The congregation did not think it was robbing the company, but that it was wrong in the doctor not to pass the applicant.

Strict honesty to the examiner is much more important than scientific assumptions.

There are several books which have been published upon the subject of examination for life insurance. Some of them are very good books, but almost all the authors have fallen into the great error of going too much into detail. Too many of these books are nothing more than elaborate works upon auscultation. That is not what is required. You, as an examiner for life insurance, are not called upon for a scientific diagnosis; you are merely to judge of the probable duration of life, and it matters not a single particle whether a murmur, which may be present about the heart, comes from the aortic or mitral valves. It

makes no difference, for if an organic murmur is present you should reject the application. You are not called upon to make a fine diagnosis, and to decide whether it be a case of stenosis or dilatation. Besides, it is hardly fair to expect a highly scientific diagnosis from the country practitioner. I do not use that word with the least degree of disrespect, but I suppose very many of you will settle in small places, which I hope will be large by and by, and it cannot be reasonably expected that the mass of the profession should be so thoroughly skilled regarding these delicate differences of sound in auscultation as to be able to make a finely accurate diagnosis. It is not expected of a man in large practice unless he can have the opportunity to verify his diagnosis by post-mortem examination. But what is expected and what is demanded, fairly and justly demanded, is that the medical examiner should be familiar with the normal sounds coming from the heart and lungs. When there is a deviation from the normal, that is sufficient. What that deviation is, is of no consequence. You hear some murmur about the heart; there is a certain amount of dullness or flatness upon percussion over some portion of the chest; it makes no difference in this connection whether there is hepatization or effusion or aneurism, but it is sufficient to know that there is something wrong in the vital organs, that the probabilities with regard to the duration of life in that person's case are diminished, and you reject the application. As I have already said, these books upon life insurance examination deal with the subject too much in detail. While thinking upon the subject of these lectures, I collected several books from our best medical examiners in this city, and there was not one of them in which the leaves were cut to any great distance. The examiners themselves had got tired of it after reading ten or twelve pages, because most of the books are nothing more than elaborate works upon auscultation and percussion. In case of doubt regarding any deviation from the normal sounds, either in the heart or lungs, your decision should be in favor of the company.

Now, all the companies have established and distributed a series of questions which the applicant must answer, and these questions are tolerably exhaustive. But you are not allowed to exercise any discretion regarding them, and it is not, therefore, worth while to discuss them in detail. All that you are called upon to do with reference to them is to see that the applicant fully understands every question which he is to answer, and to make him fully aware that any false statement in his answers legally vitiates his contract with the company. The company is not bound to fulfil its part, when the contract is made upon false presentations on the part of the applicant. Although that is all that concerns you regarding these questions, I will divide them, for the purpose of some general consideration, into three classes:

*First.*—Those which refer to the family history of the applicant.

*Second.*—Those which refer to the individual history of the applicant.

*Third.*—Those which refer to the present condition of the applicant.

First, as to the family history: that is very important. You should learn the age to which the various members of the family have lived, and a knowledge of the age which the parents reached is of great importance. There are certain families in which all the members are long-lived. In others they all die early; and yet there seems to be no special reason why this should be so. There seems to be in the individual members of some families more power of resistance to

noxious influence than in others. I may illustrate the point by the following anecdotes: Two or three years ago, while at a social gathering, the intelligence came that Dr. P— was dying in Richmond. I ventured the assertion that the doctor would not die, and based the opinion upon the fact that his constitution was such as would resist a great deal before the powers of life would be overcome. The doctor recovered. Not long after, it was said that Dr. B— was down with a slight attack of typhoid fever. I said Dr. B— is doomed to die; and he died within a remarkably short period of time. I had not seen either of those gentlemen during their sickness; but the one had the make-up and the constitution to resist the effects of disease, while the other was of a build just the reverse. It is important to study the family history of the applicant as bearing upon the question of hereditary tendency to diseases, such as consumption, insanity, epilepsy, and many others, which may be transmitted from one generation to another. If diseases liable to hereditary transmission manifest themselves in the family history, they make the applicant objectionable. If the family history throws any suggestion in this direction you should at once direct your attention to the more complete investigation of the applicant himself.

On the other hand, for example, a man presents himself for examination; he is found to have a flat chest with high shoulders, and immediately you think he has rather weak lungs. You find, upon inquiry, however, that both parents reached an advanced age; none of the family have died of consumption; perhaps the father is still alive, old, but hale and healthy, and has the same kind of a chest; and you say this is a conformation of the chest peculiar to this man or his family, and endorse his application; whereas with such a conformation of the chest, and traces of consumption in the family history, you would most certainly reject the application.

Next, with regard to the history of the applicant himself. Here you are to inquire as to what diseases he has had; and are to determine whether he has suffered from diseases which are liable to leave behind them serious results, or from those which are likely to make relapses.

If, for instance, it is found that he has suffered from acute articular rheumatism, you must be very careful about the examination of the heart. In such a case, if the heart has a rapid action, although nothing morbid can be detected by listening to its sounds, and there is nothing in the rapidity of the action, which in another person might not be easily ascribed to mental excitement, or violent exercise, or to the use of tobacco, etc., it is better to reject the application.

If the person has the least evidence of albuminuria or diabetes, the more prominent symptoms of which may break out at any time, he should be rejected. There are many other conditions which might be mentioned, but this will be sufficient to illustrate the principles upon which your examination should be made.

Lastly, we have to consider the actual condition of the applicant, and this is mainly what will engage your attention. Now, before examining the applicant, inquire why he insures his life. If he is a young man in good standing, and has a family, and wishes to insure his life for a moderate sum, such as is proportionate to his circumstances, there is fair inference that he is honest in his motive for obtaining a life insurance policy; there is no probability of any sinister, or foul design, to cheat the company, and you may be more lenient in your examination. But suppose that

a man comes and wishes to insure the life of his wife, for his own benefit; that at once looks suspicious, unless he can show good reasons for so doing. Of course you do not reject him, but the company does.

He may wish to insure his wife's life because he is supported by an annual stipend, which she receives and which ceases with her death. He may reason, I have nothing except what I receive by her good grace, and I will insure her life for my own benefit, so that, in case of her death, I may have some support. That is a very plausible reason, and may lead to concealment of defects, which can be revealed only by the most careful examination. You must, therefore, investigate the motive which induces the man to insure the life of his wife. Furthermore, you should see that the sum for which he seeks insurance is somewhat in proportion to his circumstances in life. A case in point occurred not long since. An officer in the navy insured his life to the amount of fifteen thousand dollars, in different companies. The amount was so large that his annual income was not sufficient to pay the yearly dues.

There must have been an oversight, or neglect upon the part of the company, for there was no proper inducement for the man to insure his life for such an amount. For he had no young family for which provision was to be made, and his annual income was not sufficient to pay his living expenses and the premium. That man committed suicide within three years from the beginning of his insurance, and evidently for the sake of securing to his family a large amount of money. The company contested the claim, and eventually made a compromise. After having ascertained the motive for which the insurance is secured, you will take a general survey of the man. If he looks older than the age he has declared, you must make it a point for investigation. For he has either made a mistake in the declaration of his age, which will vitiate his insurance, or he has intentionally made a false statement for the purpose of diminishing the premium. If his statement is correct, and his appearance is much older than the age he claims, it is a bad life, for it is evidence of premature decay. On the other hand, if the applicant looks younger than the age he claims, it is a good life, and the probability of longevity is increased.

In the next place, his figure must be well-proportioned. He should not be an overgrown man; over six feet in height is objectionable. If he is undersized, he is also objectionable. If there is too much emaciation, it is objectionable, because it shows a deficiency in the nutritive powers of the body. Too much adipose tissue is equally objectionable. There must be a certain proportion between the height and weight of the person, if the normal relations have been preserved. Subjoined is a table showing what the weight should be for a given height, and to that I have added the circumference of the chest, measured just below the nipple. A man measuring less than five feet and an inch in height, is under size; hence below that no proportions have been given. Assuming, then, that the person is *thirty* years of age, and measures five feet and one inch, he should weigh one hundred and twenty pounds, and the circumference of the chest should be 34.06 inches.

TABLE.

Height.	Weight in Pounds.	Circumference of Chest in Inches.
5 feet 1 in.	120	34.06
5 " 2 "	125	35.13
5 " 3 "	130	35.70
5 " 4 "	135	36.26

Height.	Weight in Pounds.	Circumference of Chest in Inches.
5 feet 5 in	140	36.83
5 " 6 "	143	37.50
5 " 7 "	145	38.16
5 " 8 "	148	38.53
5 " 9 "	155	39.10
5 " 10 "	160	39.66
5 " 11 "	165	40.23
6 "	170	40.80

Now, in this table we have represented about the normal proportion a man should have at thirty years of age, and any great deviation from this calculation is objectionable. For example: if a man, five feet, ten inches in height, should be found to weigh only one hundred and twenty pounds, and measure thirty-four inches around his chest, he should be rejected. Any sudden loss or gain of fat is objectionable, unless it can be accounted for by some passing disease. I myself, on account of exposures upon the field after the second battle of Bull Run, suffered from a slight attack of typhoid fever, and rapidly lost forty pounds in weight; but I regained it just as rapidly, and do not regard it as in any way interfering with my longevity. But a sudden loss of weight, without apparent cause, is decidedly objectionable, and is usually the precursor of early death.

This subject will be continued at our next lecture.

### Original Communications.

#### IS TYPHOID FEVER CONTAGIOUS?

By A. D. FELTON, M.D.,

SYRACUSE, NEW YORK.

WHILE acting as physician to the Onondaga County Penitentiary, in the fall of 1876, I at one time had three convicts in the hospital sick with typhoid fever; one dying, the diagnosis in his case was verified by a post-mortem.

Wishing to test the contagiousness of air respired by typhoid patients, I confined three cats in a box of barely sufficient size to permit of their easily turning around. I now had these patients alternate in blowing through tubing into the box; this was repeated for ten minutes, three times a day, for three consecutive days, the box being nearly closed for ten minutes after the sick men had ceased blowing; subsequently the cats were allowed to run at large until again subjected to the operation. The division of the annexed table, devoted to "Penitentiary Experiment," shows the result. It will be noticed that for fifteen or twenty minutes the cats were confined in an atmosphere composed almost entirely of air which had passed through the lungs of the fever patients; at all other times their hygienic surroundings were good. The symptoms manifested were: lachrymation, decided dullness, increased temperature, anorexia, and a profuse diarrhoea—which are evidently some of the symptoms of typhoid fevers; yet I cannot say their illness *was* typhoid. But grant it was, and, it is asked, if typhoid fever may be contracted from the expirations of a fever patient, why do not those who nurse the sick more frequently contract the disease? I reply, the dilution of the respired air by the atmosphere of the room may be sufficient to deprive it of contagiousness; while if the nurse were confined in a concentrated fever atmosphere, as were the cats, he might as readily contract the disease. My labors may at least further impress the policy of good

ventilation for the safety of those in charge of the sick.

Desiring to test the contagiousness of the excretions of typhoid patients, I secured several cats upon which to operate, and once a day, for four successive days, fed them half a teaspoonful of a solution of fecal matter.

The following table, arranged in the order in which I conducted the experiments, shows the result. When the same number appears the second time it indicates that that cat had been the subject of previous observation, and the figures under the head of "Sickness Commenced," "Convalescence," and "Death," indicate the number of days from the date of first eating of the matter until those several events took place. The symptoms of disease manifested more precisely the same as those of the cats used at the Penitentiary.

Reasoning from analogy, I supposed the cat could eat of healthy recent feces with impunity, as the dog is known to do, and the unfortunate example in my experiments may have been the effect of a continued

fecal diet. Previous to the unlooked-for illness of the cat fed on recent healthy faeces, I flattered myself that I should arrive at some happy conclusion substantiating the "germ theory." But with the decease of that cat my ambition waned; and yet I take exception to her premature death, for the time of her sickness was during a period of elevated atmospheric temperature, when the room in which they were confined, although ventilated, became very offensive from the diarrhoeic discharges of a dozen cats previously confined therein; to such an extent was this the case, that three convalescent cats suffered a relapse, and two, who up to this time had resisted all my efforts of communicating disease, were dumpish and refused their usual allowance of food, one having a slight diarrhoea. These symptoms lasted during the warm weather, or four days; in the meantime the cat fed on recent healthy faeces sickened and died.

Immediately following this death came the sickness of two cats fed on healthy faeces rendered putrid; but notice that they were longer in coming down and more rapidly recovered than those fed on typhoid matter; and yet there remains the fact of disease in three cats fed on healthy faeces. In all my experiments cats in good health and flesh only were used. I held a post-mortem in all cases of death, and never found any organic lesion of the intestines, but some of the mesenteric glands were swollen.

I am unable to discover whether the cat is possessed of the complements of Peyer's patches and the solitary glands; certainly I failed to find them; and I cannot say that any of these cats had typhoid fever, but I suspect that some of them had as much of the fever as it is possible for the feline to have. Sickness commenced and death followed more speedily than we are taught to expect it in typhoid fever, but the germs of disease were given by the spoonful, and needed not to wait for multiplication or fermentation, as perhaps they do in man.

Granting this disease to have been typhoid, it may not be unreasonable to conclude (the germ theory to the contrary) that while the faeces of typhoid patients are more active than those of a healthy person, yet that a sufficient quantity of healthy excretion taken into the stomach is capable of generating at least a mild enteric fever.

## Reports of Hospitals.

### BELLEVUE HOSPITAL.

#### NOTES OF PRACTICE AND PECULIARITIES OF TREATMENT.

#### FUNCTIONAL SUSPENSION OF THE SECRETORY OFFICE OF THE KIDNEY—IMPORTANT QUESTION RELATING THERETO.

A female patient had fallen into a condition in which she had passed little or no urine for a number of days, and yet from the examination of what could be obtained no evidence of organic disease of the kidney was found. The important question arose, namely, did uræmia ever occur as the result of suspension or diminution of the function of the kidney, irrespective of any organic disease of the organ? The question remained unanswered.

#### A HYPOTHETICAL CASE AND ITS TREATMENT.

Suppose that a patient was threatened with grave uræmic phenomena, or was actually suffering from

the poison, and, at the time of the visit, was unconscious, and had had or was having convulsions, what would be the treatment? It was a practical question, and the fact that it received such a variety of answers induced noting down the plan of treatment recommended by an eminent visiting physician. "Do not answer," said he, "that you would give diuretics, for they are uncertain at best; they require considerable time to produce an effect, and the patient may, from the effect of the poison, die within a very short time."

The object of treatment was to eliminate the *materies morbi* from the blood, and the most effective method for accomplishing that was to act upon the alimentary canal. Give the patient a hydragogue cathartic, and the very best is elaterium. Croton oil might answer, but it was regarded as far inferior to the elaterium; besides, it was drastic. The skin could also be acted upon at the same time. "I am disposed," continued he, "for one, to believe that *opium* renders the system tolerant of this poison, and that it is useful, not only in forestalling the convulsions, but as a remedy for controlling them when developed." Nothing new, to be sure, but interesting as corroborative evidence, and doubly interesting because spoken by one who had arrived at such an opinion only slowly.

#### HEMIPLEGIA—QUESTION REGARDING DIAGNOSIS.

A female patient, æt. 31, had incomplete facial paralysis, with paralysis of the right side of the body pretty well marked, and slight rigidity of the muscles. There was aphasia. There was a specific history of two years' standing. The attack came on while she was sitting at a table writing; appeared without loss of consciousness, but with loss of power over the right side of the body; and she found that she was unable to speak. The question pertained to the cause of the hemiplegia. It might be due to thrombosis, or to embolism, or to cerebral hemorrhage. The question of cerebral hemorrhage might be objected to on account of the age of the patient, but it was to be noted that the woman had had syphilis for two years. There was no cardiac murmur, but it was believed that embolism was not necessarily excluded by reason of that fact, for a syphilitic patient without cardiac murmur might have either thrombosis or embolism. That statement was made in recollection of two cases. The first was one in which the history was almost identical with that given in the present instance. Close examination gave no evidence of cardiac murmur. The development of the paralysis was sudden; it involved the right side of the body, and was accompanied with aphasia. Autopsy, three weeks after, revealed embolism of middle cerebral artery, and the left annicle contained an old thrombus. The origin of the thrombus was believed to be in some previous fainting-fit, and hence it was regarded as proper to inquire whether such attacks had ever occurred. The woman before us had had fainting-fits which had been quite prolonged.

Just the reverse was seen in the second case. A woman under treatment for syphilis, who also had a double aortic murmur, suddenly became paralyzed upon the right side of the body without loss of consciousness, and she was supposed to have embolism. Autopsy, however, revealed neither embolism nor thrombosis, but hemorrhage just external to the left corpus striatum. From the suddenness of the attack in the case under observation, it was thought that the diagnosis was probably between embolism and cerebral hemorrhage, for thrombosis could be reasonably excluded. The rapidity of the recovery, it was thought would assist somewhat in solving the question; for, in embolism there was usually marked improvement

within a few days, whereas in cerebral hemorrhage the recovery went on slowly. In the present case the recovery had been slow; the case was one of nine weeks' standing, and the additional fact that cardiac murmur was absent led to the diagnosis of probable hemorrhage in the neighborhood and involving a part of the corpus striatum.

For the late rigidity upon the paralyzed side, galvanism was recommended for the flexor, and faradism for the extensor muscles.

#### SYCOISIS PARASITICA.

The case illustrated the importance of one item of treatment—namely, epilation. When the patient first presented himself the disease was in the pustular stage, and there was some difficulty in diagnosis. Two or three microscopical examinations of some of the hairs of the beard were made, and finally a parasitic growth was found which decided the nature of the disease. The affected parts were at once epilated, and a solution of sulphurous acid used to destroy the plant. The result was, that at the end of four or five weeks the face was almost entirely well. Before epilation was resorted to, a variety of treatment had been instituted, but without success. Latterly he had been using the simple litharge ointment. In cases in which there is a simple abrasion, the parasiticide might reach the plant without epilation; but when the parasite had formed its nidus in the depth of the hair-follicles, extraction of the hair was regarded as a necessity in order to reach the source of the evil.

## Progress of Medical Science.

ON THE TREMBLING IN PARKINSON'S DISEASE (*Paralysis Agitans*).—M. Charcot, in a recent lecture on *paralysis agitans*, particularly insisted on the following points:

1. The name *paralysis agitans* is incorrect. The term *paralysis* cannot be properly applied to an affection in which the muscular power is preserved for a long time. The affix *agitans* is not absolutely correct, because the trembling is absent in some cases in which the correctness of the diagnosis cannot be questioned. He proposes to call the affection *Parkinson's disease*, after the English physician who first drew serious attention to it.

2. M. Charcot maintains that, as a rule, the head and neck do not take part in the tremor which affects the limbs and trunk. In those cases in which the head is observed to tremble, the oscillations are evidently communicated to it from the trunk. To prove this, he fastened a small stick, to the end of which a feather was attached, to the forehead of a patient. When the patient was left alone, the feather was in a state of unceasing agitation; but when the movements of the upper limbs were arrested in some way, as by forcibly elevating the arms and trunk, the feather was perfectly still. This experiment was tried with the same results on several patients.

3. M. Charcot laid particular stress on the fact that tremor is not a necessary symptom of Parkinson's disease. There is a form of the disease in which the tremor is so slight that it is not perceived by the patient, or in which it does not appear till after three or four years, or in which it is even entirely absent. M. Charcot gave in detail the histories of two cases in which all the symptoms of the affection were present

and had attained considerable intensity, with the exception of the tremor. This was entirely absent in one of the cases, and in the other was confined to a slight trembling of the left hand, of which the patient himself was entirely unaware. Even this slight tremor was of recent development, while the other symptoms of the disease had existed for four years.

In some cases, in consequence of the stiff attitude of the patients, of the extreme slowness of the movements, the expression of hebetude, caused by the immobility of the features, the involuntary flow of saliva, and the interference with speech, the affection has been mistaken for softening of the brain. Usually when this error has been made, the rigidity was especially marked on one side. The intellectual faculties, however, remain intact in Parkinson's disease.—*Le Progrès Medical*, December 2, 1876.

A NEW CASE OF TENDINOUS SUTURE.—M. Duplay recently presented to the *Société de Chirurgie*, of Paris, a patient, aged 36 years, who, while holding in her hand a number of canes, fell in such a way that her thumb was caught under the canes. The thumb remained flexed on the palm of the hand, and she was utterly unable to extend it. Six weeks later she consulted M. Duplay, and he found that the long extensor of the thumb no longer acted. At the level of the depression between the tendons of the long and short extensor of the thumb, on the outer side of the wrist, he discovered a slight prominence, which appeared to be the upper extremity of the peripheral end of the tendon. The diagnosis of rupture of the tendon being made, he decided to unite the two ends by a suture. The other end of the tendon was found after a long and difficult dissection; but as the distance between the two ends measured from two to two and a half inches, even when the thumb was in a position of extreme extension, he decided to unite the lower end of the tendon with the tendon of the extensor carpi radialis longior. A button-hole opening was made in the latter, and the two tendons united by means of a metallic suture. The patient subsequently suffered from a phlegmon of the back of the hand, but finally made a good recovery, and can now make use of her thumb. The metallic suture did not come away till six weeks after the operation.

M. Tillaux remarked that cases in which anastomosis of tendons is produced are rare, but added that he had performed, in the preceding week, an operation similar to the one performed by M. Duplay.—*Le Mouvement Medical*, December 2, 1876.

INFLUENCE OF BACTERIA ON THE BLADDER AND THE URINE.—The following are the conclusions of a paper, by M. du Cazal, on "Chronic Cystitis complicated by the presence of Inferior Organisms in the Bladder:"

1. The alkaline transformation of the urine in the bladder may take place when bacteria are not present.

2. Bacteria can live and multiply in urine that continues to have an acid reaction, and which may be even more acid than normal urine.

3. When introduced into a healthy bladder, bacteria are evacuated after a temporary reproduction, without producing any alterations in the urine; on the other hand, when introduced into a bladder that is in a state of chronic suppuration, they become acclimatized and proliferate there almost indefinitely.

4. Finally, they may be present in large numbers in the bladder, and very probably in the kidneys also, for months and perhaps for years, without causing either local or general disturbances.

It is evident, then, that the very important rôle which

has been attributed to bacteria, in the causation of morbid phenomena of the genito-urinary system, does not properly belong to them. The day will probably come when it will be admitted that these elements play but a purely epiphenomenal and absolutely secondary rôle, at least in the domain of pathology.—*Gazette Hebdom. de Méd. et de Chir.*, November 24, 1876.

**ON THE ACTION OF IRON IN ANEMIA.**—In the course of his researches on the blood of anæmic patients, M. Hayem has ascertained some facts supporting the opinion, that iron acts on the ultimate nutrition of the red globules. In health the number of globules contained in a cubic millimetre of blood, taken from the finger, is, on an average, about 5,500,000. When the anæmia is moderate in degree, the number of globules is about the same as in health; but they are altered in size, and contain less hæmoglobine. Thus, in one case, there were 5,352,000 globules in a cubic millimetre of blood; but the blood was not more colored than it would be with 2,500,000 healthy globules. Under the long-continued use of iron, the globules diminished in number, but they acquired their normal dimensions and became richer in hæmoglobine. The number diminished to 4,150,000, but they were equal in coloring power to 4,000,000 healthy globules. When the anæmia is extreme, the number of globules is diminished, *e. g.*, to 2,500,000. Under the use of iron a number of new, small, pale red globules first appear, and then the blood undergoes the same changes as in an anæmia of moderate intensity, so that when a cure is effected the globules are individually physiological, but are less numerous than at certain periods of the disease.

In the anæmia of fatal cachexias the blood contains globules larger than those of normal blood. When the anæmia becomes extreme, the number of these hypertrophied elements increases, and, in spite of the presence of very small elements, the average dimensions of the globules vary less from the normal than in less intense anæmias. The number of red globules then decreases daily, and iron can no longer arrest the progress of the change. Nevertheless, even then iron may cause the globules to take up hæmoglobine, and the hypertrophied elements may even possess more coloring power than healthy globules. In one case the blood contained only 414,062 globules per cubic millimetre; but the average value of each globule was 1.34.—*Gazette Médicale de Paris*, December 9, 1876.

**OBESITY AND AMENORRHEA OF YOUNG WOMEN CURED BY MILK DIET.**—M. Tarnier was consulted, some time ago, by a young woman who was suffering from albuminuria. She was very fat, and had not menstruated for several months. He ordered only the rigorous employment of a milk diet. Some months later he saw her again, and was surprised to find her quite slender in form, and presenting all the appearances of health. She had followed his directions to the letter, and the amelioration of her symptoms had been rapid. First the albumen disappeared from the urine, and then the precocious obesity disappeared. Menstruation was gradually re-established as she grew thin, and her periods had begun to occur at normal intervals.

Shortly afterwards M. Tarnier ordered milk diet to a young woman who was very obese, and in whom there was absolute suppression of the menses. She had no albuminuria. The patient lost flesh rapidly, and menstruation was perfectly re-established. These cases possess much practical interest. Milk diet must be classed among the alterative medications, but it has the advantage of being well borne by the stomach

and of not disturbing the general health. In treating albuminuria with milk, M. Tarnier orders, for the first day, one quart of milk with two portions of food; for the second day, two quarts of milk and one portion of food; for the third day, three quarts of milk and one portion of food; for the fourth day and afterwards, four quarts of milk and no food at all. In the treatment of obesity it is not necessary to adhere so rigorously to the milk diet; a small quantity of the ordinary food may be allowed. The patient may take the milk in such quantities and at such times as she likes, provided she takes the prescribed quantity per diem. The duration of the treatment will vary in different cases. If diarrhœa set in, it is a sign the treatment is not well borne. When the desired effect begins to show itself, it continues even after the treatment is suspended.—*Journal de Méd. et de Chir.*, vol. 47, 1876.

**SPASMODIC ILEUS IN HYSTERIA.**—There are several cases on record which prove that a spasmodic contraction of the intestines giving rise to the same symptoms as strangulation from an organic cause, may be produced under the influence of hysteria. At a recent meeting of the *Société de Médecine de Paris*, M. Auguste Voisin reported the case of a young, hysterical girl, in whom three attacks of this sort had occurred. The two first attacks were relieved by anti-spasmodics and purgatives, but the third one proved fatal. The autopsy revealed traces of a purely spasmodic stricture of the intestine. M. Voisin also related the history of a woman, who suffered from analogous symptoms, but in whom, with the exception of a certain *impressionability*, no trace of hysteria or of any other disease could be discovered. She complained chiefly of tympanites, which had become so extreme that it interfered a good deal with respiration; at the same time there was constipation and obstinate vomiting. This condition of affairs had lasted for several days, and was becoming more and more aggravated. The absence of any affection, that could cause a mechanical or organic stricture of the intestine, led M. Voisin to suspect the existence of a simple spasm. He introduced an œsophageal catheter into the rectum, and discovered, some distance up, a stricture that he succeeded in passing; a large quantity of perfectly inodorous gas at once escaped through the catheter. This catheterization was repeated several days in succession, and the patient was completely cured.—*Gazette Médicale de Paris*, December 16, 1876.

**TREATMENT OF SPASM OF THE GLOTTIS.**—The attacks of spasm of the glottis are much more violent than those of false croup, being accompanied by contraction of the muscles of respiration, especially of the diaphragm, and sometimes even by general convulsions. In the treatment of this affection there is rarely time to employ the various methods mentioned in the books, such as electricity, frictions, chloroform, etc., and consequently the plan proposed by M. Charon seems to be all the more practical. This physician states that inhalations of ammonia rarely fail to cut short the attack. He advises mothers, who have children subject to attacks of spasm of the glottis, always to carry a bottle of ammonia with them. He cites the case of the wife of a physician, who followed this advice, and whose child always rapidly recovered from the spasm with the help of the ammonia. Unfortunately, one day she did not have her flask with her, and while she was looking for it the child died asphyxiated.—*Journal de Méd. et de Chir.*, vol. 47, 1876.

# THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, February 10, 1877.

## THE CLIMATE OF NASSAU.

THE therapeutical effects of climate have become a matter of increasing interest and study. It is of no small importance that the physician should have reliable data upon which to base an opinion as to the probable influence the climate, etc., of any locality is likely to exert upon his patients. Too often the only statistics and reports to be had are those furnished by non-professional and interested persons.

The MEDICAL RECORD will, during the present year, send commissions to various so-called watering-places and resorts of invalids and pleasure-seekers, both in winter and in summer, whose reports will, we believe, be found of interest and value to our readers.

There are very few easily accessible places where a really dry and warm winter climate may be enjoyed. The sanatoria of our Atlantic Coast and of the West Indies are all more or less humid. Other influences characterize particularly the resorts in Florida, which detract from their comfort as winter residences. Cold north-easterly winds, laden with moisture, and even frost, may surprise the northern sojourner in most parts of Florida during any of the winter months, and unpleasantly remind one of the lack of home comforts and protection against bad weather.

It is only recently that the attention of the public has been directed to a locality now easily accessible, where violent or even moderate fluctuations of the temperature are rare, and frost is never known.

The Bahama Islands, lying entirely to the eastward of the Gulf Stream, have a range of 550 miles, from northwest to southeast, north latitude 20° 55' to 27° 31', and west longitude 72° 40' to 79° 05'. Some of the islands possess unusual interest to the historian and to the naturalist, but it is chiefly of New Providence and the capital city of the group upon it, Nassau, that we shall speak, and of its claims as a winter residence for the invalid and pleasure-seeker. It lies

in latitude 25° 5' north, and longitude 77° 20' west. It is of small extent, being about seventeen miles long by seven wide, with an area of eighty-five square miles; but little of it is cultivated, the surface being thickly covered with a luxuriant, semi-tropical vegetation, great patches of the prickly pear (*Opuntia vulgaris*), fields of cabbage palm (*Araca*), guinea grass, bushes of coco plums, guilandina, etc., etc., matted and tangled together by several species of vines, with here and there groups of larger trees. There is quite a forest of pines—the *Pinus Bahamensis*—in the middle of the island; and here, as elsewhere, the visitor is astonished at the immense number of orchids—mostly varieties of epiphytes—which cling to the branches. The botanist from the States may revel in a new flora, with hardly a familiar species to remind him of home. The invalid accustomed to the cypress and oak, and the festoons of hanging moss of Florida, will find none of these, but in their stead the stately cocoa-nut, the tamarind, the strangely rooted silk cotton tree, the royal palm, the banyan, the bread-fruit, great rows of the sea-grape on the shores. Aloes (*Agave Americana*) along the road-side, with their curiously formed shuttlecock-like young plants dropping twenty to thirty feet from their tall flower-stalks, immense tree like cacti—masses of the night-blooming cereus, like great serpents, hanging over walls, and numbers of other strange and new forms of plant-life. Oranges, lemons, and bananas abound, together with a great variety of other fruit.

This Island, as all the others of the group, is of coral origin; the limestone rock, which in some places rises to a height of sixty to ninety feet, is composed entirely of comminuted coral shells and other recent marine formations. It is quite soft and easily worked when first cut, but soon becomes hard and brittle on exposure to the air. The soil covering it is very thin; and in many places the rock is quite bare, but its surface is completely honey-combed. The vegetable mould has washed into these water-worn holes and supplies ample nourishment to the vegetation upon it.

There are no running streams whatever. In a few places the sea ebbs and flows a short distance inland, as it does also in a number of ditches cut by the government. These latter drain parts of Nassau which lie beyond the elevated portion upon which the city is chiefly built. There are two considerable lakes on the island, one at least of which is affected by the ocean tides and has brackish water. The water of the other and larger is sweet.

The drinking water is of two kinds—that from reservoirs, being stored rain-water collected from the roofs of the houses, and that from wells. The former only is generally used by the well-to-do white population, exclusively so at the hotel, and is an unusually good potable water. The well water is not safe for drinking purposes, and should not be used by visitors;

t is rain-water which has filtered from the surface and rests upon the sea-water, which appears to penetrate the porous rock everywhere. The depths of these wells obviously depend entirely upon the elevation of the ground above the sea—the body of fresh water being always found at the same level. The influence of the tides is more or less perceptible in these wells, and some of them are slightly brackish. A much more dangerous source of contamination to them, however, than the sea-water exists in the sinks and cesspools of the city, dug in the same rock, which permits portions of their contents to penetrate to the level of the water and mix with it.

The surface drainage of the city is excellent. Water soon disappears, either through the gutters cut in the stone—which, by the way, are very good—at the roadside or by percolation. It would hardly be possible to find a stagnant pool of any kind. The streets are very neat, and as both the narrow sidewalks and the carriage-ways, are cut on the native rock, and are equally hard and clean, it is more customary to walk on the latter than the former. All the roads throughout the island are of the same character, constructed by the government and kept in repair by convict labor. There is no dust.

The mean temperature during the winter months is somewhat higher than at other health resorts, as is shown by the following comparisons:

Place.	Nov.	Dec.	Jan.	Feb.	Mar.	April
Nassau, N. P.	76.8	73.6	73.6	75.7	75.4	76.1
Savannah, Ga.	58.6	51.5	52.2	54.5	60.4	67.7
Jacksonville, Fla.	64.1	54.2	56.4	56.1	64.2	67.8
St. Augustine, Fla.	64.1	57.2	57.0	59.9	63.3	68.8
Pilatka, Fla.	61.5	56.0	57.2	58.3	64.1	71.2
San Diego, Cal.	56.9	51.7	51.9	53.3	56.0	61.2

But the average mean temperature of a month may be quite deceptive. It is the diurnal and from day to day fluctuations which are of the greatest importance and have the most influence upon the health of invalids. In this particular Nassau has an advantage over any locality on the Atlantic side of the continent.

No other place we know of, so well fulfils the requirements of a winter sanitarium in this respect as Nassau, and had it also the dryness of some other resorts not so favored as to warmth, it would indeed be a very Utopia for consumptives. But while there is less moisture in suspension than in some other places which claim dry atmospheres, it has nevertheless a humid climate. Indeed it could hardly be otherwise from its situation. There is but a short twilight at the end of the day. The sudden withdrawal of the sun's rays cause an immediate and profuse dew-fall for an hour or two after sunset. The equilibrium is then restored, and there is afterwards little or no danger from exposure to the night air.

Phtlisis exists to some extent among the natives and residents. The Island is very free from malarial

diseases. Such forms of intermittent and remittent fever as exist yield readily to treatment.

The following is the Thermometric Record taken at the Royal Victoria Hotel, during the season of 1874-75. It shows the daily average of three observations taken at 6 A.M., 12 M., and 6 P.M.

Day of Month.	1874.			1875.

There are a limited number of private families with whom good board may be obtained. Visitors will generally do best by going at once to the hotel. This is a fine three-storied stone building on high ground, built in a substantial and thorough manner at government expense, and leased at a merely nominal rent, upon condition that the proprietors shall keep a first-class house in the American style. The chambers are very clean, having painted walls, bare floors, rugs at the bedside, etc., windows opening to the floor, with ventilators above them, as also above the doors. The Royal Victoria Hotel is perhaps superior to any in the South in its hygienic appointments, and is equalled by few anywhere. Its table is supplied with excellent food, well prepared.

To briefly recapitulate:—From November to April Nassau has a warm and remarkably equable climate.

- It has a moderate degree of humidity.
- Its surface is well covered with vegetation.
- Its drainage, chiefly by subsidence into the rock, is good.
- Its stored drinking water is ample in supply, and healthful.
- It is quite free from malarious and other endemic diseases.

Among those diseases likely to be favorably influenced by a residence in Nassau during the months indicated, are phthisis in its incipient stages, especially when accompanied by nervous excitability; bronchitis; some cases of laryngeal and pharyngeal catarrh; spasmodic and intermittent forms of asthma; neuralgia and rheumatism; and others which will readily suggest themselves.

#### DEATHS FROM CHLOROFORM.

THE discussion of the relations of chloroform to dentistry is not apt to lose interest for the want of new facts bearing upon it. With the recent Rahway tragedy still fresh in our minds, we are called upon to record another victim to the administration of chloroform, while in a dentist's chair. In this instance the case was that of the wife of a prominent citizen, of Rock Island, Iowa. As far as we can learn from the report furnished us, every precaution, save allowing the patient to sit in the chair, was taken to guard against the accident. The gentlemen who administered the anæsthetic was an experienced physician, and had performed a similar service to the patient before. Death appeared to be instantaneous from paralysis of the heart. If it were necessary to prove the dangerous character of chloroform as an anæsthetic in dentistry, we could hardly select a more direct case in point than the one under consideration. In the Rahway case the patient had a full stomach at the time of the accident, and there were other circumstances which more or less directly invited the issue: but in the Rock Island case there would seem to have been every chance for escape, except for the fact, that the chloroform was given for tooth drawing, and the patient was at the time on the dentist's chair. In this connection we must refer to still another death from chloroform, occurring as an accompaniment of an equally trifling operation. The account has just reached us in the *British Medical Journal*, January 20, 1877, of the sudden demise of a male patient, aged thirty-seven years, at the University College Hospital, while under the anæsthetic. The operation which called for its administration was the extraction of a small piece of dead bone from the stump of an arm. The patient was lying on the bed, and the chloroform was given *secundum artem*. He became suddenly unconscious, and when the dead bone was grasped, breathing ceased at once. In this instance also all the usual methods of resuscitation failed. At the autopsy fatty degeneration of the heart was discovered. Of course the latter condition explained the cause of death, but inasmuch as the man had taken ether before without any bad symptoms, the result has a very significant bearing upon the great dangers of chloroform. If these and similar experiences serve as nothing more than new and forcible illustrations of old and acknowledged facts, a particular reference to them will not be in vain.

#### A STATE BOARD OF HEALTH FOR NEW YORK.

MR. GULICK, member of Assembly, has introduced a bill for the creation of a State Board of Health. It provides for the appointment of one medical man from the State Medical Society, and one from the State Homeopathic Medical Society. The Board is to be further constituted as follows: Attorney General of the State, Surgeon General, State Engineer, Superintendent of Public Works, and Superintendent of State Prisons. Although there is a great show of justice in the appointments and purposes of this bill, it is evidently a partisan measure in the interests of homeopathy, and should not receive the countenance either of the State Society or of the profession generally. We want a State Board of Health, but not such one as this. As the bill is before the Committee of Public Health, it may be well for some of the influential medical men throughout the State to bestir themselves for its defeat.

#### WHEN DOCTORS DISAGREE.

LIBEL suits of laymen against members of the medical profession are by no means novelties; but the results have not recently been such as to console the supposed-to-be-aggrieved plaintiff for the expense and annoyance of his own litigation. Libel suits of medical men against one another do not so often find their way into the courts. A case of this nature has, however, occupied the attention and elicited the interest of the profession of Philadelphia within a week or two past. The plaintiff—whose name, by the way, we seek in vain in the latest medical directory of that city—was originally a graduate of a highly reputable medical institution, but became officially connected with a school for the manufacture of graduates in medicine, whose students are not on the *ad eundem* list of either of the recognized medical centres of that city. He became medical examiner of a life-insurance company, but was displaced, as he alleges, on account of a letter describing him as an old quack or words to that effect, written by a medical gentleman of excellent professional standing, who was a policy-holder in the same company. This is the central point of the libel, and, the plaintiff contends, ample ground for conviction. The judge seems, in his charge, to have avoided discussing the issue whether the plaintiff was or was not an old quack, or whether the defendant had a right to call him such, even if he thought or knew him to be one of the deepest dye, but wisely, perhaps, declared that a communication thus written by a policy-holder to a director was privileged, and in the interests of the company, which might materially suffer if the medical examinations were not skilfully and properly conducted. The jury seems to have been undecided, for the result was a disagreement on the verdict. It therefore remains an open question, in our ignorance of the motives of action of this duodecimirate, whether some of these

gentlemen may not have taken sides with the defendant that the plaintiff was really an old quack, or whether they may not have fallen into the popular error of belief, so fatal to the health and safety of thousands, that one man (with M.D. appended) is as good as another with the same appendage, whether he be a young or old quack, an advertising, unskilled harlatan, or an educated, high-toned professional gentleman.

#### ASYLUM ABUSES.

OUR attention has been called by Dr. R. L. Parsons, Medical Superintendent of the New York Lunatic Asylum, to some statements in a recent editorial, which he has reason to believe reflect upon his professional competency, and upon his ability to discharge his managerial duties.

We take pleasure, not only in disavowing any such intentions, but in bearing testimony to his fidelity as a manager, and to his earnest advocacy of all the necessary reforms. Our remarks were intended more for a general than a particular application. Although many of the abuses, particularly those of over-crowding, exist in his asylum, we are aware that he has repeatedly and earnestly protested against them. As regards the good quality and sufficient quantity of food furnished his patients, we are happy to say that we can bear equally good testimony.

## Reviews and Notices of Books.

ON COUGHS, CONSUMPTION, AND DIET IN DISEASE. By HORACE DOBELL, M.D., F.R.M.C.S., etc. Consulting Physician to the Royal Hospital for Diseases of the Chest, London, etc., etc. Philadelphia: D. G. Brinton, 115 S. Seventh St. 1877.

THIS volume, containing 216 pages, is divided into three parts. Part first is devoted to the diagnosis of bronchial and pulmonary diseases, and contains eight chapters, in which are considered the systematic examination of the chest; the diagnosis of early phthisis; the value of cavernous sounds; the importance of hæmoptysis as a symptom; winter coughs, under which head the special relation existing between bronchitis and emphysema are studied; diagnosis of narrowed air-passages; post-nasal catarrh, which is well described; ear-cough, which is worthy of recollection; and the natural course of neglected cough. In the second part the treatment of coughs, colds, and consumption is considered. The pathological conditions present in winter-cough, the early treatment of catarrh, the avoidance of colds, the therapeutic resources in coughs, the treatment of post-nasal catarrh, and the management of consumption, are taken up in regular order. In this as in the first part we have failed to notice anything specially novel, but old things are rendered new by a concise and easy style of writing.

Part third is consumed in presenting the principles of diet in disease; and here we have laid down general rules for diet in sickness, diet-list for consumptives

and diabetics, special recipes for medical food, and remarks regarding the use of nutritive enemata in disease. The book is well printed, and contains many valuable suggestions.

THE ELECTRIC BATH; ITS MEDICAL USES, EFFECTS, AND APPLIANCE. By GEORGE M. SCHWEIG, M.D., Member of the New York County Medical Society, etc. New York: G. P. Putnam's Sons, 182 Fifth Avenue. 1877.

DR. SCHWEIG, in his monograph, has set forth the claims of a new therapeutical measure, and in so doing has exhibited a commendable modesty in not regarding it as a panacea for all the ills to which human flesh is heir. He has described his method of using the electric bath; has mentioned the conditions, as far as his experience has extended, in which it is most available; has detailed the results obtained, and asks the profession to give it a trial. The advantages claimed by him for the electric bath are a more efficient and ready method of general electrization, at the same time that the electric current is under perfect control. The opinion that such benefits can be obtained by other means does not invalidate against the claims of the bath as one of the most valuable of therapeutic agents. In fact its convenience of application, its certainty of operation, and the promptness of its effects, would seem to render it superior to the ordinary methods of general electrization generally employed by the profession. The work is carefully written, and is calculated to create a new interest in the treatment of many diseases heretofore considered intractable.

TRANSACTIONS OF THE NEW HAMPSHIRE MEDICAL SOCIETY (eighty-sixth anniversary), held at Concord, June 20 and 21, 1876. Concord: Charles C. Pearson & Co., Printers. 1876.

THE volume contains the minutes of the proceedings, addresses, reports upon various medical subjects, and obituary notices. The cover of the book is devoid of all pretension, and its contents are, in more respects than one, interesting. Some of the papers give evidence of care in their preparation.

THE USE AND VALUE OF ARSENIC IN THE TREATMENT OF DISEASES OF THE SKIN. By L. DUNCAN BULKLEY, A.M., M.D., Physician to the Skin Department, Demilt Dispensary, New York; Fellow of the New York Academy of Medicine, etc., etc. New York: D Appleton & Company, 549 and 551 Broadway. 1876.

THIS essay is a reprint from Transactions of the American Medical Association for 1876, and contains a very clever statement of the author's experience in the use of arsenic in the treatment of cutaneous diseases, together with a *résumé* of the literature of the subject. It is concluded that arsenic possesses a certain value in the treatment of psoriasis, eczema, pemphigus, acne, and lichen, when proper cases are selected and the remedy is supported by a proper general treatment; that it has a less certain value in lupus, ichthyosis, sycois, verruca, and epitheliomatous and cancerous diseases; and that it is absolutely useless or harmful in the remainder of the tegumentary group. Dr. Bulkley has administered arsenic in comparatively large quantities to young children suffering from eczema, and with surprisingly good results. To a patient eighteen months old, suffering from eczema, he has given as high as five drops of Fowler's solution thrice daily, commencing with small doses, and with the happiest results. The essay is a valuable contribution regarding the remedial power of arsenic in the treatment of skin diseases.

## Reports of Societies.

### NEW YORK PATHOLOGICAL SOCIETY.

*Stated Meeting, Jan. 10, 1877.*

DR. CHAS. K. BRIDGON, PRESIDENT, IN THE CHAIR.

#### ANEURISMAL TUMOR OF THE LEG.

DR. SANDS presented a specimen of aneurismal tumor of the leg, which was especially interesting on account of the obscurity which attended the diagnosis of the disease. The patient came under his notice in Roosevelt Hospital on the 17th of December last. He was forty-six years of age, spare in habit, in somewhat feeble health, and the subject not only of surgical disease, but of albuminuria. He had been an inmate of the Bellevue and St. Luke's Hospitals previously for a tumor of the right leg. It had been regarded as a sarcoma, but there was some doubts regarding its nature, and, although the operation of amputation had been proposed from time to time, the patient would not give his consent to its performance. Fourteen years previously, he had been treated for a popliteal aneurism by means of compression of the femoral artery. This treatment was continued for nine weeks, with the result, as was supposed, of curing his disease.

About three months subsequent to the supposed cure, another tumor developed in the popliteal space a short distance below the seat of the previous tumor. This tumor, the man stated, was hard, painless, and at first freely movable. The swelling increased in size from year to year, the average increase being one and a half inches in circumference. Two years before he entered the Roosevelt Hospital he was attacked with what appeared to him to be an inflammation of the tumor, and with which he was confined to his bed for a fortnight. Ten days before his admission he had a chill, followed by a fever, with pain and increase of size of the tumor. When he entered the hospital he was so poorly that a critical examination of the leg was deferred. His temperature was 103° F., and from this time until his death it was always above the normal standard.

On December 11, four days after he had sufficiently improved to allow the necessary examination, a tumor of large size was found on the posterior or inner aspect of the upper two-thirds of the leg. Below it was found to rise very abruptly from the surface—for instance, five inches above the ankle; the circumference of the leg was five inches, while six and a half inches above the ankle the tumor measured nineteen and a half inches around.

Its greatest dimension was at the junction of the middle and upper thirds of the leg, where it was twenty-three and a half inches in circumference. From above this point it lost itself in a diffused swelling of the lower portion of the thigh. The tumor appeared to be very firm. It was for the most part smooth, hard, and then lobulated, the elevations being of considerable size. The skin over the tumor was somewhat inflamed, but otherwise healthy. On the inner lower fourth of the thigh, a point of fluctuation was found, accompanied by pulsation. Applying the stethoscope over this region, a single murmur was heard synchronous with the first sound of the heart, and resembling closely the murmur of aneurismal disease.

The history of the case caused Dr. S. to incline to

the belief that the disease was aneurismal in character. This suspicion was strengthened by the presence of pulsation and murmur; on the other hand, the long duration of the disease, the great prominence of the tumor, and the solidity of a greater portion of it, pointed to different conclusions.

December 18, eleven days after his admission, the tumor broke in two places posteriorly. On the day following there was a discharge of a large quantity of chocolate-colored fluid resembling grumous blood. This was examined microscopically, and found to contain blood discs, and a large number of corpuscles the nature of which was not determined, on account of fatty change. Solid masses were also observed, which looked like changed blood clots. Coincident with the discharge, there was a subsidence of the swelling.

Thirteen days after admission, and two days after the rupture, amputation was performed. The operation was attempted through the condyles of the femur, close to the knee; but in so doing, the knife traversed a sac which had to be dissected up, thus making the flaps shorter than was at first intended. The man did poorly after the operation. He was not uncomfortable for several days, but he had a high temperature and a high pulse. On the fifth day he was seized with pyæmia, of which he died thirteen days after the amputation.

The autopsy, made by Dr. Delafield, discovered infarctions in both lungs, and on examination of the veins there were found coagula, extending at intervals up to the point where the larger vein is joined by the saphena magna, which latter was filled with yellow thrombi. In this connection it may be stated that, in securing the vessels of the stump, it was necessary to include the femoral vein in the same ligature for the femoral artery. Dr. Abbe made a careful examination of the tumor. As near as it can be discovered, the growth has the characters of an aneurism deeply seated in the muscles of the calf. In its upper portion the sac contained a nearly spherical mass, which seemed to be free except posteriorly, where it is pretty closely attached to the aponeurotic fascia. The solid mass was found by Dr. Delafield to consist of deposited fibrine, no tumor tissue being discovered. The artery in the line of dissection, as made, was found to be obliterated and filled with a well-marked plug of fibrine. Higher up, where a section was made a second time, the artery was pervious.

It was interesting to ascertain whether there was any communication of this sac with the circulating arterial vessels. An injection of tallow and vermilion was accordingly pushed into the anterior tibial artery; although by this means the vessels of the leg were pretty thoroughly filled, none of the injection escaped into the sac. There was, then, no reason to believe that there was any communication between the sac and the vessels below the oesecision. Whether there was any articulating or other branch arising above this point, and communicating with the tumor, could not be determined.

The interesting points in connection with this case referred to diagnosis. It was one of those cases in which it seemed almost impossible to make a diagnosis before rupture appeared. Dr. Markoe, who saw the case, thought, with Dr. Sands, that the weight of opinion was in favor of aneurism rather than a tumor proper. It was, however, a mystery why the pulsation, and especially a murmur, should have existed, assuming at the time that there was no direct communication between the artery and the sac. The pulsation and murmur were detected on the 11th, and con-

tinned up to the time of the rupture of the tumor, when both disappeared. The point of fluctuation and murmur did not lie over the artery, and, even granting that the pulsation might have been simply communicated to the contents of the sac, it was still difficult to explain the murmur without supposing a direct communication between the artery and the sac. In conclusion, Dr. Sands expressed the opinion that the disease was a slow-growing aneurism which had suppurated at the same time that the communication with the artery had become obliterated.

#### PERFORATING FRACTURE OF THE ACETABULUM.

DR. SANDS presented a second specimen, with the following history: He was asked by Dr. Levings to see a gentleman, *et. 66* years, who had fallen in a dumb-waiter well, on Thursday previous. When Dr. L. was called, the patient was suffering so severely from shock that a thorough examination was not advisable; still he entertained the suspicion of the existence of a fracture of the neck of the femur. Within twelve hours after the accident the patient began to vomit at short intervals. This symptom continued until his death. Dr. S. was asked to see the patient on account of the vomiting, which was suspected, although not believed, might depend upon a hernial swelling on the left groin. The patient was ruptured on the right side, and had worn a double truss of his own invention for many years. When Dr. S. saw the patient forty-eight hours after the injury, he noted the facts already observed by Dr. Levings, *viz.*, that the limb was not shortened nor everted, and that the heel could be elevated; he did not make a very careful examination of the hip. He agreed with Dr. L. that no fracture existed. Besides the points already noted, the limb was capable of free rotary motion; there was no crepitus, and the trochanter described the arc of a circle. The right groin showed no traces of hernia. In the left groin there was a movable tumor, two inches in length and an inch in breadth, situated below Poupert's ligament, just over the saphenous opening and possibly a little external to the vessels. Although it had the seat of femoral hernia, it was soft and painless on pressure, and received no impulse on coughing. The patient assured both Drs. Levings and Sands that the particular tumor had existed for twenty years. The abdomen was carefully examined. It was slightly swollen, but no evidences of internal tumor were found. The vomited material consisted of mucus and bile. The pulse was slightly accelerated, and the temperature a fraction over 98° F. On Sunday, the third day after the injury, the pulse increased, and continued to do so, as did also the temperature. Associated with these symptoms were tympanites and other evidences of peritonitis. The diagnosis was traumatic peritonitis. This opinion was strengthened by the subsequent passage per anum of decomposed blood.

The treatment consisted of opium internally, and fomentations externally. January 10th he was suddenly seized with collapse, and died the day following.

The autopsy was made by the Coroner's assistant, and Dr. Levings obtained the specimen. The tumor of the groin was found to be composed of adipose tissue merely. This traumatic peritonitis was discovered to be caused by an extensive fracture of the pelvis, associated with the penetration into its cavity of the head of the femur, through its acetabulum. After the caput femoris had been buttoned through in this manner, it afterwards had allowed the limb to maintain its relatively normal position with the hip proper.

#### LARYNGEAL DIPHThERIA.

DR. DELAFIELD exhibited a specimen, taken from the body of a man, forty-five years of age, who was admitted to the Roosevelt Hospital January 8, and who died on the evening of the day following. His history was, that for eight years he had suffered from a cough, attended with loss of strength and emaciation. The cough had been worse than before for some months, and the expectoration was steadily increasing. The day before his admission he had a slight hemoptysis for the first time. Except for this history, and the additional statement that he had several attacks of rheumatism, nothing more could be learned. At the time of his admission he was a good deal prostrated. His temperature was normal, his pulse 100, and his respiration accelerated. His breath was offensive, and was suggestive of gangrene of the lung. After his admission he grew rapidly worse; his pulse became more and more frequent and more and more feeble, his breathing more and more rapid, and there were heard moist râles over both lungs. His skin was covered with perspiration, and he finally died in this prostrated condition.

At the autopsy both lungs were attached to the chest wall. Both were subject to emphysema as well as pneumonia. The trachea and all the larger bronchi were intensely congested and covered with a deposit similar to that seen in laryngeal diphtheria. The upper portions of the larynx and pharynx were not involved. Dr. Delafield remarked that such a condition of diphtheritic deposit could hardly be made out before death.

DR. LEWIS SMITH presented the heart and lungs, with trachea and larynx attached, removed from an infant, who died at the age of seven months, in the New York Infant Asylum. He remarked, in passing, that the case to which the specimens belonged was interesting, in connection with the one just related, inasmuch as in the Asylum which adjoined the Hospital there had been no diphtheria, with the exception to be presented, for over six months.

The infant was bottle fed, and was admitted in the beginning of December. Throughout the month it had suffered from some cough, and on Christmas a thorough examination recognized the existence of bronchitis. A mixture of carb. ammon. and citrate of iron was prescribed and an oil-silk jacket ordered. On January 1 the little patient was seized with a harsh cough and dyspnoea, which latter soon became extreme. Twelve hours after the attack the temperature was 100½° F., pulse 164, and respiration 44. There was no fibrinous exudation in the fauces, only a moderate redness of the faucial ring, and it was somewhat puzzling to account for the dyspnoea. At first, in the absence of a more reasonable explanation, it was thought that the long sickness of the child had induced supuration of the bronchial glands, and that one of these had burst into the trachea, or that a gland had suddenly increased in size and was pressing against the trachea or lower part of the larynx. There was not therefore a clear diagnosis. Finally, it was suggested that it was a case of diphtheritic laryngitis, which it proved to be. Death occurred at the end of the third day after the appearance of the grave symptoms.

#### THE DISTINCTION BETWEEN DIPHThERIC AND CROUPOUS MEMBRANES.

DR. HEITZMAN, who examined the specimens, found catarrhal pneumonia in the upper lobe of right lung and lower lobe of left lung, and a glazed diphtheritic deposit over the surfaces of the larynx and trachea, the

latter condition being associated with the former rather as an effect than as a cause; at least it was merely coincident.

DR. BEVERLEY ROBINSON could not understand why such a conclusion could be reached in this case. What was the distinction between croupous and diphtheritic exudation?

Clinically speaking, it amounted to little more than a knowledge of the fact that if croupous, the membrane when removed did not reappear within four or five days, and in diphtheria the deposit formed with greater rapidity. Further, in cases of true diphtheria the patients were apt to die, and in croupous exudation they tended to recover.

DR. HEITZMANN remarked that deposits occurring on the surface of the membrane were called croupous, while those which penetrated the substance of said membrane, causing ulceration, were styled diphtheritic.

DR. SATTERTHWAITE had been unable to make out any such distinctions. He believed that the mere penetration of the deposit on the substance of the membrane was more the result of age than of a distinct pathological condition.

DR. LEWIS SMITH was of the opinion that non-diphtheritic croup was very rare. For the past six or seven years he had seen very little croup which did not become diphtheritic, and consequently contagious.

The Society then went into executive session.

## NEW YORK COUNTY MEDICAL SOCIETY.

*Stated Meeting, Jan. 22, 1877.*

DR. JOHN C. PETERS, PRESIDENT, IN THE CHAIR.

THE Comitia Minora recommended that certificates of membership be granted to the following candidates: Drs. T. M. L. Chrystie, J. H. Swazey, Henry G. Chace, Augustus Assenheimer, G. K. Bentz, Anna D. French, C. P. R. Schoenemann, Charles Kremer, J. S. Caradine.

The following resolution, introduced by Dr. R. J. O'Sullivan and referred to the Comitia Minora, was reported by that committee and adopted by the Society:

*Resolved.* That the Medical Society of the County of New York deem it necessary that additional safeguards be adopted to protect the health of children in the public schools; and will unite with other medical societies, and with the Medico-Legal Society of New York, in their efforts to obtain such regulations, and such further legislation as may be necessary to accomplish this end."

### THE CELL DOCTRINE IN THE LIGHT OF RECENT INVESTIGATION.

DR. CHARLES HEITZMANN delivered a discourse upon the above subject, and gave not only the various theories which have been from time to time held regarding cells, cell development, and protoplasm, but his own peculiar doctrine respecting living matter.

It was assumed that living matter consisted of molecules, of which nothing was known save their chemical constitution. We had been made aware, however, that living matter possessed certain properties—namely, motion and power of producing its own. The motion was of two kinds—namely, simple change of shape, and locomotion. Change of shape was regarded as characteristic of every particle or molecule of living matter in plants as well as in animals. Locomotion had formerly been regarded as characteristic of animal living matter; but it was now known that there existed in the seeds of some low forms of

plants the capability of changing their location. The more our knowledge extended, the more the boundary wall between animal and vegetable living matter was broken down. The distinction made by Huxley—namely, that vegetable living matter was nourished from elementary food, while animals were sustained by composite substances, was rejected, for the reason that we knew really nothing as to how plants were nourished.

The second property of living matter—namely, power of producing its own—was of two kinds; it might be simply an increase in size, or increase of its own kind through propagation.

With regard to the shape of living matter, Dr. Heitzmann made reference to the cell doctrine of Schwann, the views of Virchow, Max Shultze, Brücke, and Stricker. His own theory regarding the shape of living matter stood at variance with what has preceded it, and may be embraced in the following statement:

A freshly made infusion, examined on the fourth day, having been kept in a pretty cold temperature, would be found to contain the first traces of newly formed animal or vegetable matter in the form of small, shining, yellowish, homogeneous particles, visible with a lens which magnifies from 1,000 to 1,200 diameters.

Next, particles not entirely homogeneous—the periphery remaining the same, but the centre showing signs of differentiation.

Next, particles containing one, two, or three granules. Then bodies which had a frame-work containing particles and some fluid.

On the fifth or sixth day there appeared elements capable of motion, containing granules and a nucleus. No locomotion prior to that date.

In New York the ameba had appeared more frequently without than with a nucleus. This could be seen with a low power. In Vienna the nucleus had almost invariably been present. The nucleus never changed its shape, but was really dragged after the granular contents by the movements of the body. That was an original observation.

The granules were connected with the nucleus and with each other by means of thread-like processes; and these in turn extended into and through the layer of living matter which surrounded the mass of granules, threads, and nucleus, rendering movements possible, and might be united with other bodies of the same character.

The nucleus was nothing but an enlarged granule. It was maintained that the same change could be observed in the white blood-corpuscles of the crab and newt, in the human white blood-corpuscles, in the colostrum corpuscle, in the cartilage corpuscle—although in the latter no locomotion was possible, because it was included in a matrix.

Were not those changes fanciful?

Resort had been made to two methods, for the purpose of demonstrating their truthfulness.

First, unprejudiced observers had been invited to look, and they had seen the same changes—a fact to be taken as evidence that the original observer was near the truth.

Second, independent drawings had been made by means of photography. Dr. Heitzmann had seen the demonstration of his theory upon micro-photographs of cancerous sections made by Dr. Woodward, of Washington. The distinct structure of the protoplasm, as described by Dr. H., could be seen, but when he directed Dr. Woodward's attention to it, the latter disputed the doctrine, and regarded the appearance

as nothing but evidence of coagulation or decomposition.

Dr. Heitzmann, however, firmly believed that the same structure was present in the living protoplasm, and would in the same manner be demonstrated by photography if the picture was made while the lump of matter was alive.

In view of the present theory, it was proposed to abandon the word cell, because it had no sense connected with it, and substitute the word corpuscle, ameba, granular body, or whatever term might be deemed most proper to be employed.

DR. HEITZMANN was willing to struggle for his doctrine, because he was convinced that the truth would always triumph.

### ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from Jan. 28th to Feb. 1st, 1877.*

McCORMICK, C., Asst. Medical Purveyor. Promoted Surgeon, with rank of Colonel, vice Wright, retired.

SWIFT, E., Surgeon and Major. Promoted Asst. Medical Purveyor, with rank of Lieut.-Colonel, vice McCormick.

MAGRUDER, D. L., Surgeon. Granted leave of absence for two months. S. O. 21, A. G. O., Jan. 29, 1877.

BILL, J. H., Surgeon. Assigned to temporary duty at McPherson Barracks, Atlanta, Ga. S. O. 23, Dept. of the South, Jan. 30, 1877.

WRIGHT, J. P., Surgeon. When relieved by Surgeon Fryer, assigned to duty at U. S. Military Prison, Fort Leavenworth, Kansas. S. O. 18, Dept. of the Missouri, Jan. 29, 1877.

FRYER, B. E., Surgeon. Assigned to duty as Post Surgeon at Fort Leavenworth, Kansas. S. O. 18, C. S., Dept. of the Missouri.

NOTSON, WM. M., Asst. Surgeon. Promoted Surgeon, with rank of Major, vice Swift.

WHITEHEAD, W. E., Asst. Surgeon. Assigned to duty at Fort Riley, Kansas. S. O. 18, C. S., Dept. of the Missouri.

MOFFATT, P., Asst. Surgeon. Leave of absence extended two months. S. O. 24, A. G. O., Feb. 1, 1877.

WILCOX, T. E., Asst. Surgeon. Assigned to duty at Camp Supply, Indian Territory. S. O. 18, C. S., A. G. O.

PRICE, C. E., Asst. Surgeon. Assigned to duty at Alcatraz Island, Cal. S. O. 8, Mil. Div. of the Pacific and Dept. of California, Jan. 17, 1877.

WOOD, M. W., Asst. Surgeon. Granted leave of absence for one month, and permission to apply for two weeks' extension. S. O. 10, Dept. of the Platte, Jan. 23, 1877.

ANDREWS, W. C. C., Asst. Surgeon. When relieved by Asst. Surgeon Davis, to report in person to the commanding General, Dept. of Columbia, for assignment to duty. S. O. 21, C. S., A. G. O.

ROBINSON, S. Q., Asst. Surgeon. Assigned to temporary duty at U. S. Military Academy. S. O. 21, C. S., A. G. O.

DAVIS, WM. B., Asst. Surgeon. Assigned to temporary duty at St. Louis Depot, Mo. S. O. 21, C. S., A. G. O.

### Medical Items and News.

CONTAGIOUS DISEASES.—Comparative statement of cases of Contagious Disease reported to the Sanitary Bureau, Health Department, for the two weeks ending February 3, 1877.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-Spinal Meningitis.	Measles.	Diphtheria.	Small-pox.
Jan. 27.....	0	6	76	6	14	32	3
Feb. 3.....	0	6	66	1	4	43	0

ST. VINCENT'S HOSPITAL, N. Y.—It is proposed by the present trustees of St. Vincent Hospital to erect a new building in place of the old one, located in West Eleventh street. Fifteen vacant lots at Sixty-eighth street and Ninth avenue have been purchased at a cost of \$100,000. Plans are now being prepared for the new building, which will be surrounded with spacious grounds for the recreation of the patients, and furnished with all the modern hospital improvements. The present hospital was started in 1849, by the late Bishop Hughes, and is conducted by the Sisters of Charity.

MALARIAL DISEASES IN NEW YORK DURING 1876.—Dr. Charles P. Russell, Sanitary Inspector of the Board of Health, makes the following report to the Sanitary Superintendent:

Two hundred and thirty-one deaths from malarial diseases were recorded within the year. All such cases were assigned to Sanitary Inspectors for investigation with the main object of ascertaining definitely, if possible, the locations where said diseases had originated. In order to arrive at a satisfactory conclusion in any instance, the Inspector was obliged to see personally, or communicate with the attending physician, and frequently, also, to make an inspection of the place where the death had occurred. Many physicians refused or neglected to afford any information on the subject. Quite a number of cases were excluded on account of uncertainty as to the actual cause of death, or as to its complication with a malarial element. Ninety-six cases, however, were fully investigated, and I now submit the information thus obtained. As regards locality, I have divided the city into three parts:—First, the solidly built upper portion below Ninety-ninth street and the Central Park—believed to be generally exempt from malaria. Second, that district, more or less malarious, extending from Fifty-ninth street to Harlem river. Third, the territory north of Harlem river, known as the annexed district, or Twenty-third and Twenty-fourth wards, embracing a territory prolific of malaria in almost every direction.

Deaths from remittent fever, 45; typho-malarial fever, 19; intermittent fever, 20; congestive chill, 2; malarial disease, 10.

Places of death: South of Fifty-ninth street and Central Park, 54; between Fifty-ninth street and Harlem river, 34; north of Harlem river (annexed district), 8.

Origins: From local cause, 42; in specified locations outside of New York city, 16; decidedly non-local, but place not stated, 7; uncertain, 31; from local causes, below Fifty-ninth street, 11; from local

causes between Fifty-ninth street and Harlem river, 24; from local causes in annexed district, 7."

**PRACTICE OF MEDICINE IN FRANCE.**—A measure is now in progress in France to prohibit British or other physicians from practising there, unless they have been educated and graduated in French universities.

**DR. EDWARD WARREN (Bey),** of Paris, late of Baltimore, is among the "eminent members of the profession" who are announced by the *Lancet* as its special contributors for the year 1877.

**POPULAR HEALTH ALMANAC FOR 1877.**—Mr. Frederick Hoffmann's almanac has made its appearance for 1877, and is as full as usual of interesting and valuable information for families. Not the least among the interesting things for physicians is a published list of the ingredients of several of the popular quack nostrums. We give it our unqualified approval.

**THE WOMAN'S HOSPITAL.**—The twenty-third annual report of the State Woman's Hospital, New York, shows that institution to be free from debt and in a prosperous condition. The Baldwin pavilion has been completed. Three free beds were endowed during the year. By the opening of the new pavilion, the hospital has been enabled to offer increased accommodations for the treatment of wealthier patients who find it difficult to obtain proper treatment and nursing in hotels. During the past year 289 patients have been admitted to the hospital; 162 operations have been performed; 15 deaths have occurred; and 237 patients have been discharged—leaving 51 still in the ward on October 1 last. In the out-door service 3,500 consultations have been held by the corps of assistant surgeons, and skilled treatment furnished to a very large circle of poor patients. The report of the treasurer of the Board of Governors shows the expenses of the hospital during the year, ending November last, to have been \$118,744.05, and the receipts during the same period from donations, interest on investments, and other sources, \$127,901.20, leaving a balance of \$9,157.15. The report of the treasurer of the Board of Supervisors for the eleven months, ending October last, gives the expenditures for salaries, provisions, repairs, etc., as \$24,440.80, and the receipts during the same period as \$24,506.76, leaving, with the balance of \$603.55 of the previous eleven months, a balance on hand of \$669.51. During the year the donations of private individuals amounted to \$67,357.33, the subscriptions of the "Woman's Century"—a society of ladies organized for the purpose of preventing an accumulation of debt on the hospital—amounting to \$1,855.

**FIRES IN THEATRES.**—The municipal authorities of Manchester, Eng., have made a thorough investigation of the means of egress from the local theatres and public halls, and offer certain suggestions regarding the prevention of fires and panics, which the managers are willing to carry into effect. In three of the largest theatres the stair-ways and passage-ways leading from the galleries were pronounced unsafe. The *Echo* regrets that a similar report has not been ordered in London, and suggests that it should be made somebody's business before the Surrey Music Hall catastrophe is repeated.

Recently the Union Square Theatre, of this city, has adopted all the necessary precautions against accidents by fire, and has so far profited by the suggestions of scientific men in regard to the protection of the scenery, and the provision of extra facilities for egress, that its example should be followed by every place of amusement in the country.

**AMERICAN BEEF AND MUTTON.**—The English press is almost unanimous in its commendation of the excellence of American beef and mutton. The trade in these articles of food is growing very large, 700 tons sometimes arriving at Liverpool in one day. It sells immediately, and is now marketed in London, Liverpool, Manchester, Sheffield, Birmingham, Nottingham, and many other towns.

**ALBANY MEDICAL COLLEGE.**—At the recent commencement, held January 31, thirty-eight gentlemen received the degree of doctor of medicine.

**BISMUTH IN ECZEMA.**—An ointment, containing about one drachm of bismuth subnitrate to the ounce, relieves greatly the itching and pain of eczema and many other forms of skin disease.

**MEDICAL SOCIETY OF THE STATE OF NEW YORK.**—The transactions for 1876 are now ready for distribution. Permanent members, after paying their annual dues of \$2.00 to the Treasurer, Dr. Chas. H. Porter, of Albany, will receive a copy free of other expense.

The following resolutions were passed at the last meeting of this Society:

I. Each permanent member shall pay to the Treasurer of this Society an annual assessment of \$2.00.

II. Each permanent member, who shall have paid his annual dues, shall have a copy of the transactions for the year for which he shall have paid, sent to him by the Committee of Publication.

The price of the transactions for 1876 will be \$1.50, with 15 cents additional for transportation.

**THE PRACTICE OF MEDICINE IN FLOODED COUNTRY DISTRICTS.**—For some time past the country roads in England have been almost impassable on account of floods. The rural practitioners have experienced more than ordinary difficulty in visiting their patients. In some instances boats had to be used to get to farm-houses, and extemporized bridges had to be erected to enable the physician to reach the second story dry-shod.

**A GOOD EXCUSE FOR A JUROR.**—A London juror was promptly excused from serving because he was an undertaker, and his principal business lay in a district in which small-pox was very prevalent.

**ARCTIC EXPEDITION.**—The English Board of Admiralty have appointed a committee to inquire into the cause of scurvy in the recent Arctic expedition. Dr. James Donnett, Inspector of Hospitals, R. N., is the medical member.

**POISONOUS HAIR-DYES.**—Out of twenty-one examples of hair-dye examined by the *Lancet* commission, seventeen contained lead in large quantities.

**SMALL-POX SPREAD BY MONEY.**—A writer in the *British Medical Journal* calls attention to the spread of small-pox by means of money paid out by a member of the family in which the disease exists. This is by no means a new observation, but it is well to keep it in mind in view of the chances of "stamping out" the disease by the ordinary methods employed.

**NOVEL VACCINATION.**—Forty-seven young men bargained with a physician in California to be vaccinated with the virus from the arm of a noted belle in their neighborhood. All the cases "took" splendidly, the virus obtained in each being identical in property and power with that from the original calf. Where calves are scarce this is an experiment worthy of trial.

## Original Lectures.

## EXAMINATION FOR LIFE INSURANCE.

By WILLIAM DETMOLD, M.D.,

EMERITUS PROFESSOR OF CLINICAL AND MILITARY SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK CITY.

(Phonographically reported for the MEDICAL RECORD.)

## LECTURE II.

GENTLEMEN:—At the close of my last lecture I was speaking to you with regard to the relative proportion which exists between the height, the weight, and the circumference of the chest in a well developed man at the age of thirty years. Now, when I speak of a well-developed muscular system, I do not refer to athletes, especially those who have undergone training for extraordinary efforts, such as rowing, running, prize-fighting, etc., for those belonging to this class of persons, as a rule, are short-lived men; I have never seen them reach old age. Repeated training for such efforts is very apt to be injurious. Moreover, the exclusive development of any one system is done almost always at the expense of the others. Thus it is that if a man devotes himself almost entirely to deep scientific study and neglects muscular exercise, he does it at the expense of one system, and suffers all the inconveniences attendant upon dyspepsia and its associated disorders.

When you have taken a general survey of the applicant you should inquire regarding his occupation, for there are certain pursuits which do not conduce to longevity. Among these are such as render the person liable to the accumulation of insoluble dust in the lungs. Stone and marble cutters are all short lived. Bakers are not long-lived, because their labor is mostly performed at night, and they inhale a great deal of insoluble dust.

Again, such pursuits as expose the individual to a great many accidents are non-conducive to longevity. Miners and butchers are not long-lived. Most butchers will get very fat, and that will increase the probabilities of short life already afforded by their occupation. All keepers of liquor-stores are short-lived, and most of them die of Bright's disease. They are, as a rule, too good customers in the consumption of their own wares.

The learned professions give the best average duration of life, which is said to reach as high as seventy-six years. Among the learned professions the medical, so far as the duration of life is concerned, is the very best, for the average reaches as high as seventy-six and a half or seventy-seven years. Now, understand that does not apply to the individual. All these conclusions for the individual are out of the question; but when calculations are upon multitudes the statistics are almost invariably correct.

## SUICIDES.

A few words concerning suicides. Suicide is a very awkward affair in life insurance. A man wishes to provide for his family; he gets his life insured, and then commits suicide with the expectation that his family is to receive the moneyed benefit. Now, most of the companies have inserted a special clause in their policies stating that suicide vitiates the insurance. But that does not amount to anything; all the juries are in favor of the bereaved family; they will almost always find evidence of temporary mental aberration, and of course do not regard the person as responsible

for his act. It has been alleged that suicide is always a consequence of insanity; but that does not hold good. In England it is admitted that if the suicide is committed within two years after taking out an insurance policy it is purposely done, and that view is taken upon the supposition that if more than two years elapse the suicidal intention will be given up, and the person will come to his senses and not commit the act.

The statistics with reference to suicide are rather interesting. Suicide, as may be seen by the accompanying table, is a consequence of civilization—not directly, but as the result of the vices which follow in the train of civilization. The honest farmers, the honest mechanics, the honest day-laborers, are not likely to commit suicide; it is the broker who gambles in stocks; it is the man who lives beyond his income, etc.; it is these classes which furnish the greater number of suicides. This curious table referring to suicides was made in the year 1827, and it is seen that in Russia there was one suicide in every 49,128 inhabitants.

Russia .....	1 in 49,128
Austria .....	1 in 20,900
France .....	1 in 20,740
Philadelphia .....	1 in 15,875
Prussia .....	1 in 14,404
Baltimore .....	1 in 13,656
New York .....	1 in 7,797
London .....	1 in 5,000
Paris .....	1 in 2,040

It is shown by this table that as the vices increase, which follow in the train of civilization and multiply with it, the number of suicides is materially increased.

But suicide runs in families. It may be the result of a sombre disposition characteristic of the family, or it may be in consequence of early education and the incorporation of certain ascetic and religious views. If a number of suicides have occurred in the family of the applicant, his application is objectionable, and if you do not reject him upon that ground, you should direct the attention of the company to the fact, for it is not an easy matter to escape the payment of the policy when the suicide has been committed.

## EXAMINATION MODIFIED BY KIND OF POLICY DESIRED.

The result of your examination is materially modified by the kind of insurance policy the applicant desires. If he wishes to insure for a certain amount, payable at his death, the probabilities with regard to longevity are to be taken into consideration. But it is entirely different when the person desires to insure his life for a limited number of years. For example, a man enters upon some hazardous business and invests all his property; he says to himself, if I can succeed within five years, I shall have sufficient with which to make provision for my family, but if I die within that time I shall lose all my capital, and my family will be left destitute. He wishes, therefore, to insure for only five years. That is to say, if he dies within five years, the company is to pay a certain amount, but if he lives there is nothing to pay. Of course, the statistics are just as clear upon the liabilities to death within five years as upon the average duration of human life. For it has been found that out of one thousand healthy men at the age of thirty years, a certain proportion die within five years; and upon that calculation the premium is based. In the examination of such an applicant you have less to do

with longevity than when the policy is for life, and you may accept a person for five years whom you would reject if an applicant for a life policy. Even if he is dyspeptic, or his father and mother have died of consumption, he may be accepted for a short period. Your examination, therefore, is materially modified as to whether the insurance is to be for life or for a limited number of years.

CONFIDENTIAL EXAMINATION OF THE APPLICANT.

There is one point in the printed instructions which are furnished the medical examiners of all our largest life insurance companies, to which I wish to direct your attention; and that is the *confidential* examination of the applicant.

Your examination should be confidential, and you should not allow any outside influence to bias your judgment. In the instructions it will be seen that it is directed that the agent shall not be present. The agent is an interested person; he gets a certain percentage of the premium, and does not care whether the applicant is a long-lived or a short-lived person, so long as he obtains his fee. Indeed, he is anxious to have the applicant pass, and there is always some conflict between the agent and the examiner if the applicant is rejected. Your examination should be made entirely independent of the agent. The examiner is entirely disinterested, because he gets his fee whether the applicant is rejected or accepted.

An English company some years ago established a branch office in this country, and a medical man was made agent and at the same time medical examiner. It is difficult to understand why a company should do such a foolish thing, for it is offering a premium to dishonesty.

To illustrate the workings of such a concern, I will refer to a case which fell under my observation:

A man who, three weeks before, had received a policy for five thousand dollars, came to me for medical advice, and it was found that he was far advanced in phthisis. I recommended to the company that the man should be bought off, inasmuch as he was willing to accept four thousand dollars for his insurance policy. The company declined to accept the suggestion. The man died within three weeks; the company paid five thousand dollars, and failed within three years. Men are not honest enough to hold such a double position; or if honest, their judgment is not good.

INSANITY.

It is proper to exclude insanity, but it is not always the fact that insanity shortens life. The exposure of insane people to accidents and to suicide renders it necessary that a hereditary predisposition to insanity should exclude the applicant for life insurance. There is one form of insanity which should not be excluded, and that is, if the mother has had puerperal mania. It certainly is not inherited by the sons, although it may possibly be prejudicial to the daughters.

DRUNKARDS AND TEETOTALERS.

If the applicant is an habitual drunkard, he should be rejected; nor should he be accepted if he is teetotaler; for in a very large proportion of cases the teetotaler is a reformed drunkard. A reformed drunkard is to be examined with great care, especially if his countenance is pallid, his face a little puffy, and his hands a trifle tremulous.

TOBACCO.

There is considerable difference of opinion regarding the effects produced by the use of tobacco. I do

not think that tobacco injures unless its use is carried to such an excess as to injure the constitution. What may be a moderate use for one person may be excess for another. Some persons are made exceedingly nervous by its use; but it is not the tobacco, it is the excess which gives rise to the trouble, and the excess is objectionable. Excess in the use of beefsteak is bad, and so is excess in sexual intercourse. If the insurance men were to prohibit the use of all that is bad when carried to excess, they would necessarily prohibit sexual intercourse, for there is a general admission that it is one of the most prolific sources of evil when carried to excess. They are all harmless, providing that excesses in them are excluded.

OPIMUM.

With regard to opium there is a very curious question. Now, opium eating, as a habit, is objectionable, and the insurance companies, if they know it, will not take the risk. It is not easy, however, to discover the habit. Some fifty years ago a nobleman in England, who had his life insured for a large amount, died, and after death it was found that he had been an habitual opium eater. The company, on account of the concealed habit, objected to the payment of the insurance. The opinions of medical men were obtained to the effect that it did not shorten his life; and it was then decided that the habitual use of opium was not objectionable so far as longevity was concerned. But in this country the habitual use of opium is regarded as objectionable, and it may be for the reason that most opium eaters are reformed drunkards.

PULSE.

A pulse which habitually beats over eighty to the minute is objectionable. The pulse is much more irritable in the evening than in the morning. A pulse which numbers eighty-eight while the person is standing will sink to eighty in the sitting posture, and perhaps to seventy-five when lying. An intermittent pulse may not be objectionable, but an irregular pulse is decidedly objectionable. The pulse varies, then, according to the position of the person, and it will also be found to vary according to age, as illustrated in the following table. Any marked deviation from these figures is objectionable:

AGE.	MEDIUM PULSE.
10 to 15 years	88
18 " 20 "	77
20 " 25 "	78
25 " 30 "	74
30 " 35 "	73
35 " 40 "	73
40 " 45 "	75
45 " 50 "	70
50 " 60 "	74

SYPHILIS.

I am inclined to believe that the idea commonly entertained in insurance companies with reference to syphilis is an exaggerated one. Death does not occur frequently from syphilis. It is true that syphilis will occasionally be the cause of aneurism; but aneurism is comparatively rare. You should be guided more by the fact whether syphilis has impaired the constitution, than by the mere evidence of its previous existence. I have now directed your attention to questions to be considered while making a general survey of its applicant; and at my next lecture will take up the special examination, devoting a brief period of time to points which would not be important were we called upon simply to make a diagnosis.

## Original Communications.

A CASE OF HYSTERICAL HEMIPLEGIA,  
WITH NEURALGIA OF THE TRIGEMINUS AND AMBLYOPIA,OCCURRING IN A FAMILY OF MARKED NEUROTIC  
CHARACTERISTICS.

By CHARLES S. BULL, M.D.,

SURGEON TO THE N. Y. EYE INFIRMARY; OPHTHALMIC SURGEON TO  
CHARITY HOSPITAL.

THE occurrence, both simultaneous and successive, of various neuroses in patients who are the subjects of hysteria, is a very common one, and this is an especially noticeable fact in families where there is a marked neurotic tendency in several or all of the members. It seems to be a generally recognized fact that hysteria is not only hereditary directly, but also collaterally and indirectly. We know that hysterical patients almost always number, among their near relatives, some instances of other neuroses, as epilepsy, hypochondriasis, mania, etc. In not a few instances also, some members of a family, with a tendency to neuroses, have been deaf or blind, or both. On the other hand, we sometimes meet with certain abnormal symptoms or characteristics in the children of families where the parents display no such neurotic tendency, but in which the grandparents did, and these cases must be considered as phenomena of atavism and not of direct heredity. Careful study of the neurotic manifestations in various members of a family has shown in effect, that during one, two, or three generations, the individuals of the same family at first presented nervous phenomena of a minor or less severe type, as migraine, chorea, or peripheral troubles of the vaso-motor system, but that later descendants suffered from more severe neuroses, such as epilepsy, hemiplegia, etc.

The period of appearance of hereditary neuroses varies according to the particular disease in question, but so irregularly that no rule can be laid down to guide us in our diagnosis.

The following case is presented, not because any one of the symptoms is rare, or because of the various ocular symptoms, but because of the marked neurotic character of the family, and the number of neuroses presented by the patient herself.

*Case.*—Rebecca D., *et.* 21, English, a well developed, robust-looking girl of brunette type, was first seen by me Oct. 4, 1875, and gave the following history: She had suffered for a number of years from intermittent attacks of pain and redness in both eyes, which of late have increased in frequency and severity. She was perfectly well up to her seventh year, at which time she had an attack of bronchitis, and a cough has remained ever since, accompanied by occasional dyspnea and shortness of breath. When she recovered from the bronchitis, she developed symptoms of general chorea, which lasted, with occasional intermissions, for nearly three years, and then disappeared under systematic treatment. In her thirteenth year she became partially paralyzed on the left side, both of motion and sensation. The left leg dragged behind her when she walked, but the left arm and hand were completely paralyzed. This condition lasted for two years without any change; then her menses made their appearance, and she began slowly to improve, but it was more than a year before she entirely recovered. Since then there have been fre-

quently repeated, but irregular tonic contractions of the facial muscles, sometimes occurring two or three times a day. They were never painful, but she could not speak while they were present. She has never lost consciousness, nor complained of any head symptoms until recently. During all these years the patient's general health has been good, and the general tone of her system does not appear to have suffered. The neuralgic attacks occurred in all the branches of the fifth nerve on both sides, were intensely painful, and of late have shown a preference for the right side of the face and head.

As regards the family history, the neurotic diathesis, if there be such a thing, is very marked. The father is rheumatic, and has been neuralgic since early youth. A sister of the patient died of chronic hydrocephalus at the age of fourteen, having been totally blind in both eyes for three years. Another sister died with some brain trouble in her ninth year, having been subject to convulsions. Another sister is choreic, and a brother is very dissipated, and has had convulsions.

In June, 1875, after an unusually severe attack of neuralgia of left supraorbital and infraorbital nerves, vision began to fail in L. E., and the eyeball became intensely congested. This conjunctival hyperæmia has always been preceded by an attack of neuralgia of the same side, and sometimes lasted for a number of days, though the neuralgia generally diminished in intensity after the first day. Vision grew rapidly worse, until she became entirely blind in L. E., and remained so for about four weeks, and she only began to regain the sight about a week before I saw her (Oct. 4, 1875). An examination revealed nothing abnormal externally in either eye, except the conjunctival injection of L. E. No vesicles, nor any sign of herpes; irides natural and pupils reacted well. Media clear; optic disks perhaps a trifle pale, but certainly not pathological; no pulsation in retinal vessels. R. E. V. =  $\frac{3}{8}$ ; field concentrically limited; L. E. V. = quantitative perception of light. Complains of constant occipital headache, and frequent attacks of vertigo. The patient's chest was examined and found perfectly sound, and frequent examination of the urine showed nothing abnormal. Quinine at first was administered in large doses, but with no result upon the neuralgia; and the deafness from its use being marked, it was discontinued. The constant current was then employed every day for ten minutes, from a battery of eight cells, one pole being placed along the spines of the cervical vertebra, and the other upon the closed eyelids, or in the course of the painful nerves, and this was persevered in for three weeks, as the neuralgic attacks became less frequent and lost in intensity; but there was no improvement in the vision. Before I saw her, she had been treated for nearly three months by a daily hypodermic injection of strychnia, but with no improvement.

On Nov. 1, 1875, I began the administration of the elixir of phosphorus, quinine, and strychnia, but after a week was obliged to discontinue it on account of constant diarrhoea. After an interval of six days, the neuralgia recurred with violence on R. side and lasted for four days, accompanied as usual by great conjunctival hyperæmia. During all this time there was no improvement in vision of L. E., and a slow and steady failure of vision in R. E. had appeared since the neuralgic attacks have been confined to the R. side. On Nov. 19, 1875, another aggravated attack of neuralgia in all branches of R. fifth nerve, V. =  $\frac{3}{8}$ .

On Nov. 29, 1875, vision began to return in L. E., so that large objects could be discerned. For past

week patient has been taking a drachm of potass. iod. daily in divided doses.

Dec. 5th, R. E. V. =  $\frac{1}{2}$ . L. E. slight improvement, so that she can count fingers held closely to the face. From this time up to Jan. 1, 1876, constant neuralgia in R. frontal nerve and no further change in vision of R. E.

On Jan. 12, 1876, R. E. V. =  $\frac{1}{2}$ . L. E. V. = fingers at fifteen feet. Began administration of liq. potass. arsenitis in grtt. v. doses, and ordered patient to increase each dose every day by one drop, until limit of toleration was reached. After first two days of this treatment, the neuralgia disappeared and has returned only twice since, now a period of nearly a year. The dose of arsenic was carried up to grtt. xvi. three times a day, and then continued at this mark for a week, and afterwards gradually diminished.

Since the first time I examined the patient there has been absolutely no change ophthalmoscopically from a perfectly normal fundus. One curious fact was, that soon after the final cessation of the neuralgia she had a severe attack of quotidian intermittent, which lasted eight days before yielding to quinine, and in spite of the steady administration of Fowler's solution. This was followed by an attack of bronchitis, which, however, soon yielded to treatment. On June 24, 1876, R. E. V. =  $\frac{3}{4}$  L. E. V. =  $\frac{1}{2}$ , and since then there has been no improvement in either eye, and yet no change in fundus. The neuralgia returned in R. supraorbital nerve in October, but a few days' administration of arsenic sufficed to break it up, and it has not returned since.

The case has several points of interest for the general practitioner. In the first place the marked neurotic character of the family, as exemplified in several members, and the distinct hereditary influence at work in the production of the various nervous manifestations. In the next place the various forms of functional nerve disturbance to which the patient was subject at various times. Even the bronchial trouble seems to have been of a nervous nature, for the cough, which began then, has lasted ever since, without there being pulmonary or laryngeal cause for it. Then came the chorea, followed at a longer interval by hemiplegia, which seems to have been well marked in the arm, less so in the leg. Then came the more enduring neuralgia of the trigeminus, and lastly the rather remarkable amblyopia, the latter being the only neurosis which resisted treatment. Functional amblyopia, as a result of long-continued neuralgia of the fifth nerve, has been occasionally met with, but it is sufficiently rare and almost never gives any ophthalmoscopic evidence of its existence. In our patient there did not seem to be any epileptic element, so that she could not be considered as a case of what Charcot calls "hystero-epilepsy, in which ocular troubles are not at all uncommon. Such patients also are apt to present signs of deafness and diminution of taste and smell on one side. What the change is in hysterical amblyopia, and where it is, whether central, or in the optic nerve or retina, we do not know. Primarily it is, of course, an abnormal nervous condition, which probably reacts on the vascular system. The arterial and capillary systems perform their healthy functions so long only as they retain the normal influence of the nerves supplying them, whether locally or generally. If the supply of nervous influence fails, the capillary system of a part loses its normal tone and the vessels here dilate. This, perhaps, may account for the condition of the injected conjunctiva but not for the amblyopia, for at least within the eye there is no dilatation of vessels visible.

A few words in regard to the hemiplegia. Here there was probably a spasm of the blood-vessels, for although this may not have been the efficient cause, it most likely had something to do with this condition of functional derangement. It is certainly an uncommon and anomalous condition, and is usually confined to a single limb, such as an arm or leg. When the leg and arm of the same side are affected the weakness is said to be more marked in the leg, whereas in our patient the arm was the most affected. It is also said to occur more frequently on the left side, and this was the case also in our patient. Wilks relates a case of hysterical hemiplegia in Guy's Hosp. Rep., Vol. XVII., 1871-72, in a young woman *æt.* 30, who had been long subject to migraine. A numbness appeared in the little finger of the left hand and gradually involved the whole arm. Several months later the left leg also became numb in the same way. For some months before Wilks saw her there had been paralysis of the entire left side, including the face and eyelids. She had had one convulsion, followed by unconsciousness. On admission, June 14, 1871, there was left ptosis, equal pupils, eye movable, left hemianæsthesia and hemiplegia.

There is a very interesting case recorded by a French author some time since, though where reported has escaped me. The patient was a woman *æt.* 34, who had suffered from tri-facial neuralgia from childhood, the pain being limited to the superior and inferior maxillary divisions of the fifth nerve of left side. The pain was not continuous, but the paroxysms were very violent, and were complicated by the loss of smell for pure odors, deafness on the left side during the paroxysms, profuse salivation and lachrymation, partial dilatation of left pupil, and paresis of left half of sphincter oris and left levator anguli oris. There was also an increase of temperature on left side of face, but no hyperæsthesia or anæsthesia anywhere else. The patient's father and mother both died young of asthma, and four children preceding her died young.

*Arningand* mentions a particular form of intermittent hysterical phenomena in which the vaso-motor troubles become very prominent, and, in fact, constitute the whole malady, and such must be the localized injections of the ocular and palpebral conjunctiva in our patient during and after an attack of neuralgia of the frontal nerve.

## ON THE CURE OF TUBERCULOSIS OF THE LUNGS BY INDUCING CALCIFICATION.

By C. BOTH, M.D.,

NEW YORK.

My attention was drawn to this subject by a post-mortem examination, made at Wuerzburg by Virchow, I think. The subject having died from some injury, presented, quite unexpectedly, a lung which had previously been the seat of tubercular inflammation, and which was then entirely healed by a spontaneous process of calcification. I remember well the stir this case made at the time, and it left the impression on my mind that a result which nature brings about spontaneously, we must necessarily be able to effect with certainty, provided, first having discovered the conditions under which, and the method by which, she accomplishes this—we thus succeed in imitating her.

Dr. John Hughes Bennett, in his "Pathology and Treatment of Pulmonary Tuberculosis, 1853," Blanch-

ard & Lea, 1854, pages v. and vi., says: "Although it was generally considered by the profession that no remedy and no plan of treatment yet employed could be depended on in cases of consumption, it was obvious to the author that if the process employed by nature could be discovered, and then imitated by art, we might ultimately arrive at the true principle of cure." In this same book he publishes cuts of pathological specimens, prepared by himself, representing this spontaneous process of calcification. Similar opinions have been expressed by Piorry, Thiercelin, Alison, Churchill, Cannstadt, Virchow, Niemeyer, and many others.

In 1853, while trying to introduce to the profession of Boston what is now known as cellular physiology and pathology, I was reminded that such was of no practical value. This had not occurred to me before, and I thereupon resolved to test the same at once. While at work arranging matters for this purpose, a tubercular consumptive presented himself for treatment. With the idea derived from the post-mortem examination above referred to fresh in my mind, I concluded at once to try to effect calcification in this case. The attempt proved successful, the patient still living to-day, perfectly well, in Frankfort-on-the-Main.

In considering this case it appeared to me that the re-establishment of capillary circulation in the parts affected was the cardinal point; for when lime is to be deposited as the curative element it can only be carried there by the blood-vessels. I remembered from experiments which I had made on frogs' legs and the lungs of water lizards, while engaged in anatomical researches under the guidance of Dr. Stilling, to have observed that capillaries, becoming obstructed, would swell and burst, allowing the blood-globules to escape in the tissue meshes. This observation, which I first published in Boston, in 1860, before an audience of about one hundred and fifty physicians, and again in 1863 before the Massachusetts Medical Society, was afterwards published in Berlin (1866) under Cohnheim's name, and again by the Smithsonian Institute (1870) as the latest European discovery.

Upon reconsideration of the mechanism of respiration I became convinced that the blood, through the long serpentine lung capillaries, could not be propelled by the action of the heart, but by respiration only; that, in respiration, the nitrogen of the air was the agent of mechanical pressure, and the oxygen the chemical factor; that oxygen was a thinner gas than nitrogen, and therefore able to penetrate the air-vesicles, while nitrogen could not. This supposition, arrived at by mere logical calculation, has since been proven correct by experiments made by Graham, whereby he increased the amount of oxygen in the air to forty per cent. by filtering air through India-rubber shavings. (*Scientific American*, May 1, 1869, p. 279). From this I arrived at the conclusion that stagnation of circulation in the lungs must occur wherever the mechanism of respiration ceases, which again must finally lead to an accumulation of blood globules in the vessels, thus forming a thrombus and occasioning distention and rupture of the vessel, with escape of blood-globules into the tissue meshes; that tubercles, therefore, were nothing but escaped blood-globules lodged in the meshes, where they remain and act as foreign bodies. This view has since been corroborated by Professors Petroff, Schueppel, and Waldenburg.

The white and red globules, together with the serum, fill out one or several meshes; the serum next becomes absorbed or evaporated; the red globules lose

their pigment (which is afterwards found in tubercles); they then shrivel and their contents coagulate, appearing somewhat like nuclei. The cells themselves change into pus cells, or, according to surrounding influences, into fat cells; they next either decay and infect the neighboring tissue cells, or they may calcify, thus becoming inert. We thus find an explanation for the gray, the yellow, the softening and the calcified tubercle. The latter form, being inert, is the one we seek to produce. An absorption of fresh tubercle cannot occur because there is stagnation of circulation and paralysis of the nerves surrounding the tubercle. The tissue meshes being permanently filled out with blood, occasion simultaneously a collapse of the air vesicles and bronchioles, with more or less catarrhal inflammation of the latter as a consequence.

I therefore determined to commence treatment by clearing these bronchioles and vesicles as much as possible, in order to again procure pressure upon the meshes and blood-vessels. For this purpose I employed the muscles of the thorax to expand the chest, and thus force air into the bronchioles and vesicles by *suction*—not by pressure. The result of this is a long deep cough with increased expectoration, which is at first of a slimy, mucous character, afterwards more dense, and cheesy—at times bloody. The muscles are exercised in order according to their layers, viz.: first the pectorales, serrati, cucullaris, and latissimus dorsi; afterwards the intercostal and deeper vertebral muscles; and finally, the whole together with the abdominal muscles and the diaphragm. Neither machines, clubs, nor dumb-bells are employed; the weight of the body alone being used to increase the power of suction, which becomes enormous by practice and correct application. The deep inspirations which follow the tension of these muscles occur with relaxed bronchial muscles, thus opening the bronchi, while all machine manipulations occasion contraction of the bronchial muscles, which prevents the air from entering in those parts where we most desire and need it. These muscular exercises are not by any means easy, even for a well and strong person, as it would appear at first. In the case of a consumptive, with nearly paralyzed muscles, it requires a great deal of careful and intelligent guidance on the part of the physician. In directing the exercises due consideration must therefore be given, in each case, to the mental, physical, and nervous condition of the patient. Too much force causes pleuritis and possibly hemorrhages; too little, has no effect on the points of the lungs. The methodical tension of the muscles not only cleans in time the bronchioles and vesicles of phlegm and pus, but reawakens, to some extent, the paralyzed nerves around the tubercles, inducing again a partial capillary circulation. This constitutes the *local treatment* employed.

The *constitutional treatment* is by far more difficult and complicated. The condition of the glands and blood is in no two cases alike, nor perfect in any. Our first object is to ascertain the state of the intestines and liver. If these are in good order, so much the better; if not, they have to be regulated first. This accomplished, our next point is the state of the blood. Sometimes this is found in a relatively good condition, more often it is not. It is not generally sufficiently oxidized, and is loaded with the remains of used protein substances, which ought to have been excreted, but were not for want of higher oxidation. To reach this I employ citric, uric, and ponic acids. These acids contain a higher proportion of oxygen than any constituent of the blood, and are the only ones which do not coagulate albumen. I generally use citric acid,

because it is the easiest to be obtained. I give the juice of from three to twenty lemons at a dose according to circumstances. The lemons are peeled, the juice pressed out, and taken without water or sugar. No unpleasant feelings should follow its administration. In proportion as these acids increase oxidation and excretion, fresh and new blood material should be furnished in the diet, so as to balance absorption, digestion, and excretion.

Finally, lime and silica are introduced in an easily digestible form, which is the organic; any mineral given in any other form cannot become assimilated. We know that certain plants grow in certain places, and contain certain minerals which are found in those places; such plants disappear the moment these minerals are deficient in the ground. Every farmer knows that witchgrass destroys the fertility of the land, by absorbing from it the phosphates and sulphates of lime and silica; for this very reason the juice of witchgrass is one of the medicines used to supply the organism with these minerals; and if we consult the history of therapeutics we shall find that Extract. graminis is one of the oldest popular remedies for consumption. A popular and very peculiar remedy, once a secret medicine, formerly officinal, was the white excrement of dogs. Its officinal name was Album græcum, or magnesia animalis. How people came to use such stuff is very strange; yet it really contains organic lime, and it almost seems as if natural instinct had led humanity to seek unconsciously for organic lime as a remedy in consumption.

Another lime-containing plant is Achillea millefolium, also an old popular remedy. Thistles contain silica; plants growing in swamps, sulphates. I use the extracts of them in their crude state, as alcohol excludes the albumen, which contains the salts wanted. The following is an average formula as I use these extracts:

R. Extr. graminis,	
" trifolii fibr.,	
" millefol.,	
" card. benedicti.....	āā ℥ i.
Tartrate of soda.....	℥ i.
Aqua.....	℥ liiiss.
Tinct. amara.....	℥ iiss.
M.	

Dose: one to three tablespoonfuls daily.

There are many other plants which might be used for the same purpose, but I prefer these on account of their bitter extractive matter, which seems to act somewhat as a substitute for bile on the intestines.

In all diseases of a constitutional character we find the great sympathetic partially or wholly overtaxed, so as to induce either partial or general lack of activity. It must, therefore, become a cardinal object to lighten as much as possible the work of this nerve. This can be done by avoiding overtaxing unnecessarily its power in general, and by dividing and balancing its work properly. Upon comprehension of this depends the therapeutical effect of a correct diet, digestion, and excretion. I forbid for this reason any and all stimulants. They are for the sympathetic what the whip is for the horse. A good horse requires no whip, and the whip makes a lame or poor horse no better. The failures in the treatment of constitutional diseases are owing to a lack of appreciation of this fact. The idea of curing a diseased lung without securing the good-will of the sympathetic, is like fighting a battle without a well-drilled army to rely upon. A well-balanced and normal action of the sympathetic is the foundation upon which we cure a constitutional disorder, and upon no other basis whatsoever. Can we

regain this we become master of the situation; if not, nothing will be of any use. In other words, we must establish the balance between *absorption, assimilation, and excretion*, without which nothing can be done in consumption, nor in any other constitutional disease.

The favorable result reached in my first case has led me to give special attention to the subject, and I have employed this method for the last eighteen years in all cases coming under my treatment, and have arrived at the following conclusions, viz.:

1. No case of chronic affection of the lung is curable unless we are able to re-establish vesicular breathing, or, at least, to force air into, and between the affected portions, so as to again induce, at least, *partial* circulation of blood and air.

2. No case is curable in which a nidus of pus exists *outside of the lung-tissue proper*, and within the reach of the general circulation, but beyond the reach of the knife or trocar; whether this be a lymphatic gland, or an abscess in the brain, pleura, liver, etc.

I consider all other cases curable by the employment of the above described method of both local and constitutional treatment. If it fails, it is either due to one of the above causes, or else to an imperfect execution of this method. For this latter reason it is not adapted to hospital or dispensary practice, unless special arrangements are made for such purpose.

I have employed this treatment with the same results in Boston, the West Indies, Western part of this State, and also in New York City. It requires no change of climate, machines or apparatus, of any kind. Previous to 1869, I treated any patient presenting himself, regardless of diagnosis or conditions; my rate of cure, to those of death then stood 40-60. Since 1870 I have changed my plan, and select only such cases as promise a possibility of cure. Doubtful cases I take on trial for about two months; if they do not reach a precalculated standard, I advise them to desist from further attempts at cure by my method. The consequence of this has been, that since that time, with almost nothing but so-called hopeless consumptives on my hands, I have not lost a single case.

The average time required for a lung to calcify is about six to twelve months. My first case required thirteen months. The shortest arrest ever reached was in the case of the wife of a lawyer in Rochester, N. Y., transferred to me by Dr. Knichling, which required only six weeks, after resisting the usual modes of treatment for two years. This, however, was an entirely uncomplicated case of tuberculosis of only two years' standing.

This method requires the strictest attention and management, as well as a great deal of patience and endurance on the part of both physician and patient. They are required to keep a book from day to day in which pulse, meals, excretions, and general symptoms are daily noted. This keeps them attentive, and allows an easy review of the case at any time. They go out-doors in any kind of weather, and at all seasons, without extra precaution, and I *never* knew one to be injured by so doing. In fact, I require them to go out. All symptoms of febrile paroxysms, night-sweats, and sleeplessness soon disappear without the use of quinine, sulphuric acid, tannin, ergotin, or any other drugs; neither do I use any morphine. The patients must get stronger every day, the pulse and temperature tend towards normality; otherwise things are not progressing as they should. The condition of a patient dismissed as cured is as follows:

1. Percussion remains about the same, sometimes more tympanitic.

2. Auscultation denotes sharper respiration in the

parts affected; expiration distinctly audible. No râles or crepitation.

3. Pulse and temperature are normal.

4. Strength greatly increased, without gain in weight to any considerable extent; muscles hard and powerful.

5. Voice is clear, strong and enduring.

6. Patients present no outward symptom of sickness, and are fully capable of following their usual avocation or business.

7. As yet I never knew any of them to exhibit symptoms of returning lung affection; they, however, are advised to keep up their exercises.

8. Cough entirely ceases, and is the last symptom which disappears.

I have in my possession only one pathological specimen of lung treated by the above method. This case was under my treatment nine months, when he withdrew, without my consent. He gave up treatment in 1861. In 1863 he remarked to me that he could never have had consumption, but that his case must have been one of bad dyspepsia. In 1864 he died from tubercular affection of the lymphatics of the mesenterium. His lungs contained fifteen encapsulated caverns, and show the effect of the treatment to the naked eye, although they have been in alcohol all that time. I only saw him again three weeks before his death, which was caused by exhaustion from five months of diarrhoea.

As will be perceived, this method of treatment has no specific character, but consists rather of a chain of manipulations and procedures which, linked together, have for their aim a reanimation of cellular activity generally. There can be no doubt but that any organism has the strongest tendency to preserve itself, and if we support this we are able to achieve results which sometimes overreach the most sanguine expectations; at least such has been the case in my practice. I look upon cough as the natural tendency to clean and refill the lungs with air; upon fever as the tendency of the whole cellular vitality to recover its balance. Neither is an enemy to the organism, but only a symptom of cellular activity and vitality, and disappear as soon as its natural purpose has been accomplished.

More minute details than here given may be found in previous papers on this subject. viz.:

## Progress of Medical Science.

LOCOMOTOR ATAXIA.—M. Charcot insists that it is wrong to speak of the loss of co-ordinating power as the fundamental symptom of locomotor ataxia, or, as he prefers to call it, *tubes dorsalis*. In many cases this loss of co-ordinating power does not appear until five, ten, fifteen, or twenty years after the cerebral symptoms, the shooting pains, the enteralgic attacks, and sometimes the arthropathies have made their appearance. His own researches and those of his pupils have

demonstrated that the sclerosis of the posterior columns, the characteristic lesion of locomotor ataxia, co-exists with the manifestations of shooting pains before the co-ordinating power is impaired. The disease cannot, therefore, at that time be said to be in a prodromal stage; it is really an existing disease. Moreover, ophthalmoscopic examination of tabetic patients who are afflicted with amblyopia or amaurosis reveals a pearly aspect of the papilla, a progressive atrophy, from which alone, even if all other symptoms be absent, the diagnosis of locomotor ataxia in process of evolution may be made. Like Trousseau and Duchenne, M. Charcot believes that locomotor ataxia, when subjected to proper treatment at an early period, may be cured or be arrested in its course, or will at least prove less rebellious to treatment. Hence the great importance of recognizing the disease as early as possible, before the loss of the co-ordinating power.—*Gazette Médicale de Paris*, Dec. 16, 1876.

OPINIONS ON THE EMBOLIC THEORY OF CHOREA.—Dr. J. Hughlings Jackson, of London, adduces a few facts in reply to Dr. Barnes, who claims that the embolic theory has been destroyed by Ogle, Dickinson, Bristowe, and others. Though in a large number of brains examined by eminent physicians and pathologists, no "discoverable emboli were in the small vessels," they may still have existed—in fact, he claims that Dr. Dickinson did discover constant morbid appearances, which were like those produced by emboli, if regard was had to the size of the arteries plugged. Tuckwell, however, found emboli, and Bastian saw plugging in three cases, and regarded them as instances of thrombosis. It is possible, Dr. J. adds, that this latter hypothesis may supersede that of embolism.

Dr. Mackenzie, of London, has at present a case of chorea under his charge, which he believes throws light upon the relation of embolism and chorea, as cause and effect.

The mother had valvular disease, followed by paralysis, which was regarded as certainly due to embolism of the middle cerebral artery. The child has valvular disease, and, upon the death of the mother, the emotional excitement was followed by an attack of chorea, which might be explained by the vascular excitement causing vegetations and coagula to be swept off from the mitral valve. The muscular area affected by the choreic movements was the same as that affected by the mother's paralysis, viz., the area of distribution of the middle cerebral artery. As, however, to the query, why should the same cause in one instance produce hemiplegia and the other hemi-chorea? it is answered, that in the one case a large artery was plugged and the nutrition of the nervous matter so seriously affected as to completely deprive it of its functions; while, in the other case, only the smaller branches or arterioles were blocked, no necroses of nervous matter ensuing, but merely impaired or altered nutrition, leaving an unstable condition of the nerve matter and its result, spasm.—*British Medical Journal*, December 23, 1876.

THE TREATMENT OF PSORIASIS BY CHRYSOPHANIC ACID.—The rebellious nature of psoriasis, under most forms of treatment, gives especial interest to the following communication: Mr. Squire, of the British Hospital for Diseases of the Skin, records two cases, in which he appears to have been remarkably successful. The remedy is said to be used in India for ringworm; at least the goa-powder is recommended for that purpose, and it contains, according to Sir J. Falner's analysis, 85 per cent. of chrysophanic acid. The cases are as follows: A clergyman, aged 53, presented

patches of psoriasis, which had existed for years all over his face and body. Neither arsenic nor medicines of any kind were given, but an ointment of the acid. After six applications he appeared to be completely cured, and so speedy and satisfactory a result he does not appear to have ever attained before, either by the use of arsenic, or Harrogetat, Aix-la-Chapelle, or other waters. The ointment is of a light golden yellow color, without smell, while the common tar ointment is sticky and smells strongly. Another patient, a woman of thirty, was successfully treated by the goa-powder ointment in the strength of three drachms to the ounce (about nine times the strength used in the tropics).

After a week's use of the remedies, without any other whatever, she was rid of nearly every one of the patches. The remedy in this case, however, was pushed hard, and after the seventh day she had a burning sensation in the skin, so that treatment was suspended. All the patches were quite white and smooth. This piebald appearance, resembling the markings of leucoderma, would, Dr. S. thinks, disappear in a few days.—*British Med. Journ.*, Dec. 23, 1876.

**MILK DIET IN BLADDER DISEASE.**—Dr. George Johnson, of King's College Hospital, in a recent lecture, alluding to the use of an exclusive milk diet in various forms of disease, such as chronic diarrhoea and dysentery, typhoid, and acute albuminuria, instanced some cases of bladder trouble in which amelioration followed rapidly after the free and almost exclusive use of milk. A young lady of seventeen had suffered for many months from severe attacks of pain over the bladder, so that during a period ranging from two to five hours, she would pass water every two, three, or five minutes. Opium pills and hot hip-baths afforded only temporary relief. Oysters or fish always brought on an attack. Her urine was acid, and contained pus. She was advised to try a milk diet exclusively, the use of hot hip-baths at night, and occasional opiates, which thus far were the only remedies that had given her relief. She also took some pills containing camphor and the extract of henbane. About nine months afterward she was fully restored to health, and the urine was perfectly normal, though she was liable to relapses, and then, upon resuming the exclusively milk diet for twenty-four hours, was again restored to her usual good health. Two other instances are given in which milk alone was given for chronic cystitis, and no other medicine whatever. In each case the cure is recorded as absolute; and, after one case, the patient was able to resume ordinary plain fare and drink his wine at dinner as usual. The milk is to be taken cold or tepid, and not more than a pint at a time. With some persons the milk agrees better after it has been boiled. If the milk be rich in cream and cause heartburn, headache, diarrhoea, etc., the cream may be partially removed by skimming. The cream, however, overcomes the tendency to constipation. Dr. Johnson thinks that the milk diet will be made use of by surgeons who are contemplating lithotomy or lithotripsy, so as to lessen, as much as possible, the inflammation and catarrh resulting from the mechanical irritation of the mucous membrane of the bladder.—*Lancet*, Dec. 6, 1876.

**AN EPIDEMIC OF CONTRACTION OF THE EXTREMITIES.**—Prof. Jules Simon reports the following interesting facts: Early in October of last year an epidemic of contraction suddenly broke out in a school for little girls, situated in the rather damp and unhealthy village of Gentilly. No cases occurred in an adjoining school

for boys, or in two neighboring boarding-schools. The contractions came on suddenly, were preceded by formication, and accompanied by severe muscular pains at a distance from the point of contraction, and lasted several hours. In many cases both hands were affected, in some the feet were affected, and in rare cases the affection was unilateral. The flexed fingers could be straightened by the use of force; but this increased the pain. Sensation was not affected. The general condition of the children affected remained good. On one day twenty-eight little girls suffered from the contractions.

The affection could not have been a simulated one. The children, who were all only about ten years of age, could not have remained voluntarily for hours in such a condition, and would have been unable to describe the formication and the pains at a distance from the point of contraction. The transitory nature of the phenomena, and the absence of paralysis and of disturbances of sensation, show that the contraction was not symptomatic of an anatomical lesion of the nervous system. The malady was evidently essential in its nature, and the limitation of the cases to one school indicates that some of the cases might have been caused by contagion and irritation. This is the more likely, as the inhabitants of the village were greatly frightened by the epidemic. They thought it was due to a supernatural cause, to the maledictions of some teachers, who had formerly taught in the village, but had been obliged to leave. In consequence of the rapid spread of the epidemic the school was closed, and from that time no new cases occurred. The children already affected recovered rapidly under the influence of simple isolation at home.—*Gazette Médicale de Paris*, December 2, 1876.

**ARNOLD ON THE PLASMATIC CHANNELS IN CONNECTIVE TISSUE.**—There has been so much discussion of late on the permeability of vascular walls and the relation between blood-vessels and serous spaces, that Professor Arnold, of Heidelberg, has undertaken a new series of experiments to clear up some of the obscurity that covers these matters. The generally accepted fact that both white and red blood corpuscles, together with granular matter, escape from the vessels, both in health and in inflammation, was not questioned, but the object sought was to determine the paths they pursue outside the vessels and the openings through which they make their exit. A series of injections were done, upon both living and dead animals, with various soluble and insoluble substances, such as the indigo sulphate of soda, Berlin blue, soluble starch, and sepia. They all led him to the same conclusion, that in the serous membranes, the skin, the subcutaneous connective tissue, the fasciæ, tendons, and cornea, there are paths which are capable of being injected by the way of the blood-vessels. He also thought it was evident that the cells of connective tissue were colored by the injected matters, and that the paths represented spaces lying in the intervals between the connective-tissue bundles, and they were connected with the blood-vessels and lymphatics by delicate processes which entered the vessels in the intervals between the endothelial cells. He accordingly rejects the idea that the connective-tissue corpuscles represent a hollow system of plasmatic channels. The corpuscles rest upon the connective-tissue bundles, to which they are firmly attached on one side, while the other side is turned towards the serous channels. These views, therefore, correspond very closely in many respects with those originally advanced by Recklinghausen.—*Archiv f. Path. Anat.*, lxxviii., 4, 1876.

## SANITARY CARE OF SCHOOL CHILDREN.

THE discussion of the question of the sanitary care of school children promises to result in some good. Two bills are now before the State Legislature, one fixing the minimum age of scholars at six years, the other advocating the creation of the office of Medical Superintendent. Both measures commend themselves to reformers as necessities. It is well known that our public schools are overcrowded. Especially is this the case in our primary departments, in which children of all ages are assembled, from four years and upwards. With our foreign population such schools are looked upon more as nurseries than as educational establishments. As soon as a child can talk, can be taught to sit still, and can be made to go through with the barbarously contrived calisthenics, it is sent to the nearest primary to spend the better part of the day. Aside from the great injury inflicted upon such children by such forcible confinement, and by insufficient ventilation, they occupy places which rightfully belong to older ones. The passage of a law fixing the age of admission to a more reasonable limit than at present prevails will operate for good in two ways: directly upon the infants whose tender age unfits them for school exercises; and indirectly upon those who have a right to attend, but whose chances for being benefited mentally and physically are diminished in proportion to the crowded state of the school-room. The importance of any bill having for its object such reforms cannot be lightly estimated, and deserves the active support of every physician throughout the State.

In regard to the necessity of organized and authoritative sanitary inspection of our schools, we have said so much that it seems hardly necessary to do more than congratulate ourselves upon the prospect before us. The voice of the profession has at last been heard in the legislative halls, and the chances that its earnest

advocacy of the measure may be successful are reasonably good. The arguments in its support are so strong that they have only to be properly presented to insure conviction in the minds of our law-givers and bring about the long wished-for result. As a significant omen, we are pleased to know that the Board of Education, far from offering any opposition to either bill, has at least consented to give both its unqualified approval. So far, then, the outlook is promising, and the labors of the active agitators of reform may not be in vain.

## ABOLITION OF THE OFFICE OF CORONER.

AT a recent meeting of the Municipal Society, a report was made upon the "duties and abuses of the coroner's office," in which it was recommended that the said office be abolished. This is certainly a bold movement, but one for the making of which there appear to be the best of reasons. As an office which has been monopolized by politicians and managed entirely in the interests of party organization, it is not difficult to understand that gross abuses of power and privilege are the result. The coroner's duties, as defined by law, are, first, a medical inquiry as to the cause of death; and, second, a judicial inquiry as to the perpetrator of the crime. Not only are these duties widely different in their nature, but their discharge involves the highest amount of discretion and the greatest appreciation of the responsibilities involved. How far they fall short of the actual purpose and intent of the law, we all know.

The manner in which these duties are performed is thus referred to by Dr. Stephen Smith, who makes the report:

"We find that the certificates of death by coroners are largely in excess of the actual number of deaths by violence. In 1873 there were 2,546 of these certificates, and but 1,161 deaths from violence, and the other 1,385 needed only a proper medical examination to determine their nature, and most of them were not reasonably suspicious in their nature. Another method of increasing inquests is, where a number are killed by a common casualty, to hold inquests on each body."

In commenting upon the necessity of improving the present practice, Dr. Smith very properly said that "nothing could be done properly without scientific knowledge accurately obtained by persons properly qualified. This duty should be performed by the Health authorities. It had been demonstrated that scientific investigation would detect the cause of obscure murders, and a systematic mode of ascertaining the cause of doubtful cases of death should be established. The present defective and corrupt system should be swept away, and a better one substituted. The Board of Health should ascertain, in the first instance, the cause of death, and the Police Justices should be given power to supplement this action when necessary in suspected criminal cases. In doubtful

cases an attorney should accompany and aid the medical officer, and the body be removed to Bellevue for a thorough examination. The coroner's jury should be abolished. A provision of the State Constitution creating the office of coroner existed, and a proper amendment should be made."

To this end the following resolution was unanimously adopted:

*Resolved*, That the Judiciary Committee take the necessary steps to secure the passage through the Legislature of an amendment to the Constitution abolishing the office of coroner in cities of upward of 10,000 inhabitants."

The gross abuses connected with the office of coroner it is not necessary to detail. They are patent to every one acquainted with the manner in which inquests are usually carried on. The latitude allowed these functionaries affords them almost unlimited opportunity for the exercise of individual discretion, bribe-taking, and every other species of official corruption common with men of indifferent morals and low instincts. We are not surprised to learn that some of these officers have made fortunes with what they call legitimate fees, and that they are willing to spend large sums to secure an election. But even allowing assertions in regard to these points to be unfounded, we have the strongest argument in favor of abolishing the office, in the fact that there already exists in our larger cities, especially in New York, all the necessary machinery for the proper performance of its duties with little or no extra pecuniary tax upon the citizens. The best of arguments, however, fail when weighed against political expediency. Our best hope in the success of the project is the sensible recommendations which are made by the committee, and the temperate and judicious means taken to secure the end.

## Reviews and Notices of Books.

**THE THEORY AND PRACTICE OF MEDICINE.** By FREDERICK T. ROBERTS, M.D., B.Sc., M.R.C.P., Fellow of Union College, Assistant Physician and Assistant Teacher of Clinical Medicine at University College Hospital, London, etc., etc. Second American Edition. Philadelphia: Lindsay & Blakiston. 1876.

WHEN the first edition of this work appeared we took occasion to speak of it in the highest praise. We are not disappointed to find that another edition has been called for, and that the author has been encouraged to make it even more worthy of appreciation by the profession. The original plan, already sufficiently presented to our readers on a former occasion, has been adhered to, while many of the articles have been almost entirely rewritten. The printing of the volume in one-sized type is a recommendation in its favor for easy reading and less confusion in the separation of what appear to be notes from the original text. An entirely new chapter has been introduced on the diagnosis of acute specific diseases, in which is given an elaborate and carefully prepared diagnostic table of the principal fevers.

**NOTE ON THE ADMINISTRATION OF PHOSPHORUS.** By EDWARD M. SQUIBB, M.D. Abstract from the Proceedings of the American Pharmaceutical Association for 1876.

A STABLE and uniform preparation of pure phosphorus has long been a desideratum. This demand has stimulated Dr. Squibb to researches which have resulted in a stable solution of phosphorus in cod-liver oil, having a strength of one part in a hundred. The details of its preparation are contained in the pamphlet under notice, a perusal of which will well repay any one who uses, or proposes to use this powerful and, heretofore, very uncertain and treacherous agent. Solutions in vegetable oils, which have been used to a considerable extent by the profession, are liable to lose their strength by oxidation, or, as sometimes happens, to undergo changes which lead to the formation of bodies much more active and poisonous than phosphorus itself. The "Note" also contains a formula for dispensing the phosphorized oil in a solid form.

**PUBLIC HEALTH REPORTS AND PAPERS, Vol. II.** Presented at the Meetings of the American Public Health Association, in the years 1874 and 1875. New York: Hurd & Houghton. 1876. 8vo, pp. 532.

SINCE its organization, in 1872, the American Public Health Association has been singularly fortunate in developing an interest in the discussion of sanitary and social problems, not only among its members, but with the public at large, which, we may safely say, is unparalleled in any similar undertaking. Although composed of a mere handful of earnest, thoughtful, and persevering workers, it has succeeded in keeping alive an interest in the great work of reform, which is the surest prospective of even more increased and widespread influences. We are reminded of an obligation to tender renewed congratulations upon the success of its more recent doings, by the recent appearance of a large, valuable, and handsomely printed volume of transactions, being the second in the series. As the title indicates, this work contains the reports and papers presented to the Association during the years 1874 and 1875, together with which is a record of the proceedings from its organization in 1872 to the close of 1875. It is impossible to review the contents of the book in detail, but it is sufficient to say, in commending its perusal to our readers, that all the articles are of an unexceptional value. The subjects are divided under the following general heads: I. Public Health, Care and General Physical Conditions relating to Hygiene. II. Educational, Social, and Physiological Subjects affecting Public Health. III. Sanitary Engineering, Drainage, Sewerage, and Cleansing. IV. Hospitals, Sanitary Care of Contagious Diseases. V. Reports on Yellow Fever. VI. Public Health Laws and Sanitary Administration. The authors of papers upon subjects classified under these headings comprise the first men in the country, in their respective departments—physicians, clergymen, engineers, and educators.

**OPHTHALMIC and OTIC MEMORANDA.** By D. B. ST. JOHN ROOSA, M.D., Professor of Ophthalmology and Otology in the University of the City of New York; Surgeon to the Manhattan Eye and Ear Hospital; and EDWARD T. ELY, M.D., Assistant to the Chair of Ophthalmology and Otology, University of the City of New York; Attending Surgeon to the Class of Eye and Ear Diseases, Eastern Dispensary. New York: William Wood & Co. 1876.

This little manual should be in the hands of every student and practitioner, for it will be found to be one of the most convenient books for reference that

has been produced. Its contents are systematically arranged. It is divided into two parts, and each part is divided into three chapters. It has a bibliography, a glossary, and an index. It is concise, and yet sufficiently comprehensive to be almost entitled to the name of treatise.

**CYCLOPEDIA OF THE PRACTICE OF MEDICINE.** Edited by Dr. H. VON ZIEMSSSEN. **DISEASES OF THE PERIPHERAL CEREBRO-SPINAL NERVES.** Vol. XI. By Prof. WILHELM HEINRICH ERB of Heidelberg, Baden. Translated by Mr. HENRY POWER, of London, England. ALBERT N. BUCK, M.D., New York, Editor of American Edition. New York: William Wood & Co., 1876.

The larger portion of this volume of 608 pages is devoted to functional disorders, or neuroses of the peripheral nerves. The advances that have been made of late years in neuropathology have, according to the author, been mostly in the collection of clinical data, and not in the discovery of morbid changes in the nerve structures themselves.

Indeed, the affections that are held to have a definite lesion are so few that the description of them occupies only about 35 pages. They are classified under the headings of hyperæmia, inflammation, atrophy, hypertrophy, and neoplastic formations.

Under the functional disorders are noted neuralgias in general; neuralgias of special nerves, and anæsthesias, neuroses of the nerves of special sense, and neuroses of the motor nerves, under which head come spasms, cramps, tetany, contractures, general and special paralyses.

**CYCLOPEDIA OF THE PRACTICE OF MEDICINE.** Edited by Dr. H. VON ZIEMSSSEN. **DISEASES OF THE CHYLOPOËTIC SYSTEM,** together with Chapters on Diseases of the Naso-pharyngeal Cavity and Pharynx, Laryngitis Phlegmonosa, Perichondritis, Laryngea, Ulcerations and Tumors, and Neuroses of the Larynx. Vol. VII. By Prof. HERMANN WENDT, of Leipsig; Prof. W. LEUBE, of Jena; Dr. O. LICHTENSTEIN, of Tübingen; Prof. ARNOLD HELLER, of Kiel; Prof. H. VON ZIEMSSSEN, of Munich; and Dr. A. STEFFEN, of Stettin. Translated by ARTHUR V. MACAN, M.D., of Dublin; EDWARD W. SCHAEFFLER, M.D., of Kansas City; A. BRAYTON BALL, M.D., and LEWIS A. STIMSON, M.D., of New York; and J. SOLIS COHEN, M.D., and ARTHUR VAN HARLINGEN, M.D., of Philadelphia. New York, 1876.

This volume is not strictly devoted to the chylopoëtic system, as may be inferred from the above title. Indeed, there are no less than 334 pages devoted to other subjects, belonging more strictly to the preceding number. The remaining pages are devoted to Disorders of the Stomach and Intestines, by Prof. Leube; and Constrictions, Occlusions, and Displacements of the Intestines, by Lichtenstein. There is also an article on Intestinal Parasites, by Heller. The contributions of Leube, Heller and von Ziemssen are unusually readable, and as numerous excellent woodcuts accompany them, the volume is made very attractive. The German editor seems to have been remarkably fortunate in securing for these three volumes the assistance of writers and teachers so widely and favorably known.

**CYCLOPEDIA OF THE PRACTICE OF MEDICINE.** Edited by Dr. H. VON ZIEMSSSEN. **DISEASES OF THE CIRCULATORY SYSTEM, TOGETHER WITH CHAPTERS ON WHOOPING-COUGH, DISEASES OF THE LIPS AND CAVITY OF THE MOUTH, AND DISEASES OF THE SOFT PALATE.** Vol. VI. By Prof. ROSENSTEIN, of Leyden; Prof. SCHROETTER, of Vienna; Prof. LEBERT, of Vevay; Prof. QUINCKE, of Berne; Dr. BAUER, of

Munich; Dr. STEFFEN, of Stettin; Prof. VOGEL, of Dorpat, and Prof. WAGNER, of Leipsig. Translated by GEORGE W. BALFOUR, M.D., of Edinburgh; EDWARD G. GEOGHEHAN, M.D., of London; THOMAS DWIGHT, M.D., of Boston; J. HAVEN EMERSON, M.D., and GEORGE G. WHEFLOCK, M.D., of New York; and J. SOLIS COHEN, M.D., of Philadelphia. New York, 1876.

DISEASES of the heart form the subject of the first 342 pages, and are treated by Rosenstein, author of the "Pathology and Therapeutics of Kidney Diseases;" Schroetter, the well known Laryngoscopist of Vienna; and Lebert, the author of "Physiologie Pathologique," also a contributor to the first volume of this series. The subject is exhaustively treated. Quincke follows with Diseases of the Arteries, Veins, and Lymphatics; and Bauer, with Diseases of the Pericardium. Vogel, the author of a Manual of Diseases of Children, after sketching the diseases of the lips and cavity of the mouth, gives a short chapter on Angina Ludovici, which is rather new in text-books. Wagner closes the book with an account of the diseases of the soft palate. In discussing the nature of croupous and diphtheritic lesions, he differs diametrically from Oertel, Hueter and others, asserting that the parasitic evidence of diphtheria rests upon weak evidence, and that the specific poison of the disease is still entirely unknown.

**MODERN THERAPEUTICS: A Compendium of Recent Formulae, Approved Treatment, and Specific Methods in Medicine and Surgery,** etc. By GEORGE H. NAPHEYS, A.M., M.D., etc. Fourth edition. Rewritten and enlarged. Philadelphia: Dr. G. Brinton, 1877. 8vo, pp. 609.

THE very comprehensive title of this work is singularly applicable to its character and value. The writings of Dr. Napheys have always been distinguished by the features of practical worth and by appreciation of the wants of busy workers in the departments of preventive and curative medicine. We are truthfully informed in the preface that the volume differs from ordinary works on the practice of medicine in being devoted *exclusively* to practice; that is to say, the various diseases are discussed only with reference to applicable treatment. To give the greatest value to suggestions under this head, numerous favorite prescriptions of practitioners of this and other countries are introduced. The untimely death of the author, when the work was but one-third through the press, threw the responsibilities of its completion upon Dr. Brinton, of Philadelphia, to whose skill, discrimination, and learning is due its very satisfactory completion. The present edition is very much increased in size over its predecessors, and bids fair to become proportionably popular with the profession. As a handbook of therapeutics, pure and simple, it is invaluable to every practising physician.

**PORT-WINE MARK, AND ITS ORBLITERATION WITHOUT SCAR.** By Dr. BALMANNO SQUIRE, Surgeon to the British Hospital for Diseases of the Skin. London: 1876.

THIS pamphlet describes a new method for the cure of this deformity. Briefly it is as follows: "Freeze the part (by the ether spray apparatus), then scratch it with an ordinary cataract needle in parallel lines, about one-sixteenth of an inch apart; then place a piece of blotting paper on it before it has thawed, pressing the paper firmly on the scratched skin for five minutes. Next day repeat the operation, if necessary, the lines being in an oblique or transverse direction to the origi-

nal scratches." The scratches *do* not divide the entire thickness of the skin. The part must be well frozen, both that the operation may be painless and to avoid any hemorrhage. In applying the blotting-paper, the pressure should be absolutely perpendicular to the surface, for if the slightest lateral traction be made, the miniature incisions will gape slightly, and so become plugged with minute wedge-shaped clots of blood, with resulting indelible linear scars. After relaxing the pressure, the paper should be allowed to remain for at least half an hour. Then it should be thoroughly wetted and gently removed, traction being made in the same direction as the incisions, so as not to tear them open. The thin clot of blood covering the part after removal of the paper should be gently washed off with a camel's hair brush and cold water, then a film of glycerine should be carefully applied.

Dr. Squire claims that "no scar whatever remains; the deformity has vanished, as if charmed away by incantation; and the patient is cured, absolutely and certainly, for the rest of his life, within a fortnight after the efficient performance of this simple operation." It seems to us that this plan of procedure should have a fair trial by the profession.

**THE FUNCTIONS OF THE BRAIN.** By DAVID FERRIER, M.D., F.R.S., Member of the Royal College of Physicians, etc., etc. With numerous illustrations. New York: G. P. Putnam's Sons, 182 Fifth Avenue, 1876.

DR. FERRIER, whom we all recognize as having brought order out of chaos in the question of cerebral localization, presents us with his first book, and in fact it is about all we have in the English language upon the subject of cortical centres, with the exception of scattered articles in the medical journals. He is one of the majority who believe in the existence of cortical centres, and with him are gathered Hitzig and Fritsch, Hughlings Jackson, and others; while, on the other side, Brown-Séquard, Dupuy, and several of the French school violently oppose them. Ferrier's experiments were chiefly made upon the monkey, an animal which has proved himself to be of much value to the cerebral physiologists.

Dr. Ferrier has detailed a long series of experiments, all of them of the most interesting character. He first considers the anatomy of the cerebro-spinal centres, and, beginning with the reflex functions of the cord, passes to the discussion of phenomena which follow disease or removal of certain important parts of the cerebellum and cerebrum. The remarks upon the pathology of *M. nière's* disease, and the various modifications of visceral impressions and their relation to this form of auditory vertigo, are well considered. By far the most interesting parts of the book are chapters vii., viii., x., and xi. We have here a full discussion of the question of cerebral function, and the chapters under discussion are conspicuous for their clear, simple, and connected presentation of the subject. Our author, for the first time, details experiments in regard to the centres of smell and taste. On page 290 a most admirable diagrammatic explanation of the nervous centres is given.

In these days of constant change it is difficult to keep pace with the advances of cerebral physiology. When such men as Brown-Séquard present a theory one day, and change it almost the next, there is a great deal to render our study discouraging.

Ferrier's book, with its simple style and logical reasoning, really forces us to believe that after all there is something definite in the study of the nervous system.

**CHEMISTRY, GENERAL, MEDICAL, AND PHARMACEUTICAL,** including the Chemistry of the U. S. Pharmacopœia, etc. By JOHN ATTFIELD, Ph.D., F.C.S. Seventh edition. Philadelphia: H. C. Lea.

THE seventh edition of this excellent little manual is sufficient attest of its popularity and utility. Its value lies in the practical character of its directions for chemical manipulation; and, in these days of advanced pharmacy, it should be kept for reference by every person engaged in the compounding of drugs.

**CHEMIA COARTATA,** or the Key to Modern Chemistry. By A. H. KOLLMYER, A.M., M.D. Philadelphia: Lindsay & Blakiston.

A CONVENIENT little book for reference. Well-arranged and condensed tables, giving the symbols, names, and synonyms, tests, mode of preparation, etc., of various inorganic and organic substances from the bulk of the book; and a table of poisons, with antidotes and treatment is added, together with directions for the conversion of different weights. The table of poisons is somewhat indefinite, and several false statements and omissions are made.

**PRINCIPLES OF HUMAN PHYSIOLOGY.** By WILLIAM B. CARPENTER, M.D., F.R.S., F.G.S., etc. Edited by HENRY POWER, M.B., London, F.R.C.S. American Edition, with Notes and Additions by Francis G. Smith, M.D., Prof. of Institutes of Medicine in the Univ. Penn., Fellow of Coll. Phys., etc. Philadelphia: H. C. Lea, 1876. 8vo, pp. 1083.

IT is only within the past few months that we had occasion to notice the last London edition of this popular work, and now it comes to us in a somewhat different shape as an American edition, with "such additions as seemed advisable to supply the material which has accumulated both in Europe and in this country since the publication of the English edition." In speaking of the work as an American edition, we have only to assure our readers that Prof. Smith has evidently done his utmost to fulfil the expectations of every progressive student of physiology.

**A PRACTICAL TREATISE ON THE DISEASES, INJURIES, AND MALFORMATIONS OF THE BLADDER, THE PROSTATE GLAND, AND THE URETHRA.** By S. D. GROSS, M.D., LL.D., etc. Third Edition, revised and edited by Samuel W. Gross, A.M., M.D., Surgeon to the Philadelphia Hospital. Philadelphia: H. C. Lea, 1876. 8vo, pp. 565.

THIS is an old work, which has been out of print for many years, rejuvenated by the author's son, who has rewritten the greater portion of it. Comparing this with the former edition, the omission of the descriptive anatomy of the urinary organs is a noticeable feature. Altogether this is an improvement, and gives opportunity in a moderate sized volume of treating of subjects of more importance to the practical surgeon. The entirely original chapters in this edition are those on tumors of the bladder and of the prostate gland. They are well arranged, clearly written, and full of valuable information and of practical hints. As a guide for the surgeon who may be called upon to treat diseases of the genito-urinary tract, the work is fully up to the requirements of the times, and cannot fail to maintain the rank which it has earned for itself years ago.

**TRANSACTIONS OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.** Third Series, Vol. II. Philadelphia, 1876. 8vo, pp. 177.

THIS is the second volume of the new series, and comprises the papers read before the College, from October, 1875, to July, 1876, all of which are of singular

interest, are written with care, and are deserving of study. The contents and scope of the volume can be obtained by the following list of contributions:

I. A case of Empyema, cured by Drainage-tube, etc., by Dr. Jas. H. Hutchinson. II. Evacuation of an Hepatic Abscess through puncture in the Abdominal Walls, by Dr. Louis Starr. III. Report of Committee on Epidemics for 1876, by Dr. R. A. Cleemann. IV. Excision of Knee-joint and Amputation of Thigh, for Disease of Knee-joint, by Dr. John Ashhurst, Jr. V. Excision of Knee in Adult, by Dr. H. Lenox Hodge. VI. Therapeutic Uses of Compressed Air, by Dr. J. Solis Cohen. VII. Note on Anatomy of Perineum, by Dr. Harrison Allen. VIII. Local Injuries of Nerves, etc., by Dr. S. Weir Mitchell. IX. Hysterical Affections of the Eye, by Dr. Geo. C. Harlan. X. Gunshot Wounds of the Thoracic and Abdominal Cavities, by Dr. W. S. Forbes. XI. Case of Calculous and Cystic Disease of both Kidneys, by Dr. J. Cheston Morris. XII. Sarcomatous Tumors, by Dr. J. Ewing Mears; and lastly, XIII. Case of Diabetes Insipidus treated by Ergot and Gallic Acid, by Dr. James Tyson.

Dr. Mitchell's article is illustrated by a beautiful chromo-lithograph and woodcuts, the latter also embellishing the articles of Drs. Hutchinson, Ashhurst, Hodge, and Mears. The volume is very tastefully printed.

## Reports of Societies.

### NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, February 1st, 1877.*

DR. S. S. PURPLE, PRESIDENT, IN THE CHAIR.

#### THE RELATIONS BETWEEN PSEUDO-MEMBRANOUS CROUP AND DIPHTHERIA, AND THE VALUE OF TRACHEOTOMY IN EACH.

DR. AUSTIN FLINT opened the discussion upon the above subject with the remark that, probably, its leading object would be to determine whether pseudo-membranous croup and diphtheria were two diseases, distinct from each other, or were essentially one and the same disease. Dr. Flint regarded them as essentially distinct diseases: 1, histologically; 2, clinically. Speaking from a histological stand-point, he was willing to concede that the local process in the two diseases did not involve any essential pathological difference. With that view, the question therefore was to be settled by clinical evidence; and the reasons for regarding them as essentially two distinct diseases were chiefly the following:

Pseudo-membranous croup occurred rarely except as a sporadic disease; it never prevailed epidemically.

Diphtheria prevailed as an epidemic, and was generally admitted to be a disease communicable by inoculation and by means of infectious miasm.

Pseudo-membranous croup occurred only rarely before two, and almost never after seven years of age. Diphtheria attacked persons of all ages not infrequently.

Pseudo-membranous croup was a local disease, and the fever which attended its progress was symptomatic—the constitutional symptoms being proportionate to the amount of fever.

Diphtheria was to be regarded as an essential fever, and the local affection was its anatomical characteristic.

The question of the presence or absence of micrococci was purposely passed.

In pseudo-membranous croup death occurred by asphyxia.

In diphtheria death occurred by asthenia, often without laryngeal affection.

Pseudo-membranous croup was not accompanied, both with regard to degree and extent, by an exudation within the fauces, perhaps anterior and posterior nares, as occurred in diphtheria. The occurrence of an exudation upon the vulva, perhaps upon the anus, upon excoriated surfaces, etc., did not belong to the history of pseudo-membranous croup.

Enlargement, sometimes suppuration, of the lymphatic glands was peculiar to diphtheria. Hemorrhages did not occur in connection with pseudo-membranous croup, nor did paralyses. Regarded from a clinical standpoint, therefore, it was no more proper to consider a case of pseudo-membranous croup as one of diphtheria than to regard a case of dysentery in which there was a plastic exudation upon the mucous membrane as diphtheria.

The discussion might be brought within narrower limits by considering whether the *laryngitis* of diphtheria differed from that of pseudo-membranous croup; in other words, was the *laryngitis* the same in both diseases? That question was to be answered only by macroscopical and microscopical observation. To render the investigation yet more laborious, pseudo-membranous croup as a complication of diphtheria was not of infrequent occurrence, nor was the fact of such complication inconsistent with the belief that they were distinct diseases.

With reference to the value of tracheotomy in each, two questions arose:

1. Was tracheotomy of any value in these diseases?

2. If the answer was in the affirmative, of how much value was the operation?

In answer to the first, it was maintained that some lives had been saved by the operation in pseudo-membranous croup, and the same thing could be said regarding diphtheria, although the chances of success were much less than in the former disease. It was to be regarded, therefore, as an operation having a certain value, but the amount of value was a question for secondary consideration. Dr. Flint claimed, however, that although the chance of success might be ever so small, the operation should not be withheld. It was the duty of the physician to place before the patient or the friends of the patient the fact that at the proper time, and under proper circumstances, tracheotomy was a means of saving life. The operation relieved suffering and contributed to euthanasia, and for that reason alone it was justifiable. The amount of value was to be determined only by trustworthy statistics showing the proportion of instances in which recovery followed its performance.

DR. A. JACOB continued the discussion by first referring to the question of tracheotomy. Of its value he was convinced, and out of sixty-eight cases which he had reported, twenty per centum of the lives had been saved, for he felt quite certain that that proportion would have died had not the operation been performed. He had performed the operation about two hundred times, and in deciding whether it should be resorted to had been guided by a single indication—namely, imminent suffocation. When his operations had been performed he had felt certain that no benefit was to be derived from the use of medicines. He did not ask how long the process had lasted; or how thick the membrane was; or whether the membrane might be expectorated in a day or two; or whether it looked yellow or white or black; or whether complications were present—pneumonia, for example—but the only

indication by which he had ever been guided had been imminent suffocation. It was the same indication which led one to cut the rope by which a person was suspended from the ceiling.

Pneumonia had been regarded as a complication contra-indicating the operation, but he had seen a case recover in which he was aware that such complication was present when the operation was performed. There were some apparent contra-indications besides pneumonia, such as great enlargement of the glands about the neck, a certain septic character of the disease, local gangrene, cutaneous diphtheria, etc. Such complications certainly impaired the prognosis, but did not reduce the responsibility upon the part of the physician, which he would incur for refusing the operation. It was true that when the septic character of diphtheria was well developed the chances of recovery were diminished. But the septic character was frequently the result of inhalation of material from the nose and pharynx, and under such circumstances the operation might be the immediate cause for improvement in the symptoms. Early age was not an objection, for one case had been reported but lately, by Dr. Winiwarter, in which the child was only ten months old, and recovered after the performance of the operation, not to speak of a number of cases under a year or two, recorded in earlier literature. There were cases in which he refused to operate, such as those in which the symptoms of exhaustion were more prominent than those of suffocation. In such cases the operation was useless and not indicated.

Dr. Jacobi then proceeded to consider some of the statements made by Dr. Flint while giving the clinical evidence, which sustained the belief that diphtheria and pseudo-membranous croup were two distinct diseases. It had been stated that paralysis did not follow "croup"; but it was for the very simple reason that very few patients sick with "croup" lived until they could become paralytic. The paralysis would not appear until the apparent recovery had been established. In diphtheria the cause for the paralysis was two-fold: it was either the result of the local affection involving the soft palate, or it was the result of diphtheritic affection of the nervous system, and which appeared at the end of the fourth, fifth, or sixth week, perhaps later. Patients sick with pseudo-membranous croup did not live so long, and most of them did not have sufficient exudation upon the soft palate to give rise to early paralysis. Dr. Jacobi admitted that the lymphatic glands did not become enlarged in croup as in diphtheria, but when the inflammation was confined to the laryngeal mucous membrane the laryngitis did not result in glandular swellings, for the reason that there was very much less of lymphatic connection between the larynx and the neighboring tissues than between the nose and pharynx and such glands. The bronchial glands might become enlarged during life in a case of croup, and had been found so.

The hemorrhages which occurred in diphtheria took place only after considerable injury to the mucous membrane and sub-mucous tissue by the deposit. Such injury did not occur so commonly in the larynx in croup, and there was no deep-seated gangrene. Thus it could not be expected that hemorrhage would occur from the larynx in croup.

It had also been claimed that there was no cutaneous complication in croup. That was true in a majority of cases; but Dr. Jacobi further stated that he had seen the wound, after tracheotomy, in cases of supposed "croup," covered within twenty-four hours with a diphtheritic exudation; and it was a fact well known that when blisters were applied in the treat-

ment of croup the vesicated surface might become covered with a membranous exudation.

Dr. Jacobi then referred to the fact that the best histologists were unable to agree as to what was seen when examining the exudation of croup or diphtheria and the mucous membrane with which it was connected, and gave some explanation why the membrane was easily removed in some instances while in others it was of a very permanent character. Imagine that the process, whichever it might be, took place in the trachea; there the muciparous follicles were so abundant that the epithelium inevitably became elevated, lifted off, and it had been called "croupous." When we had to deal, however, with a surface beneath which there were no such follicles, especially when covered with pavement-epithelium, as upon the margin of the epiglottis, the membrane did not prove croupous, but diphtheritic, and would not be easily removed from the surface to which it was attached. A thin membrane deposited over the margin of the epiglottis would remain for a long time, whereas in those localities abundantly supplied with muciparous follicles the membrane would be lifted up and easily removed. Upon the vocal cords no mucus was secreted; there were no lymphatics present; and the membrane, when formed, lasted for a long time; no general poisoning followed, and no glandular swellings were developed. Where different results followed one and the same diphtheritic process, it was due to difference in the anatomy of the parts in which the process was located. When the process occurred upon the tonsils, it was innocent, because there was no lymphatic connection with the remainder of the system. When it occurred in the nares where the lymphatics were abundant, glandular swellings were developed in a short time, and septic disease, because absorption took place rapidly.

Dr. Jacobi arrived at the following conclusion: That croup and diphtheria were identical processes, and yet the clinical features of the two forms of disease would differ from each other. The clinical results would differ according to the anatomy of the part affected and the general symptoms which were developed in consequence thereof. There were cases of diphtheria in which the entire blood was poisoned, and yet there were but trifling local manifestations of the disease. In such cases we should not make a parallel.

Diphtheria was a general blood disease, resulting from the inhalation, in his opinion, of a chemical poison. The first symptom of the disease by which it was diagnosed was the membrane, no matter where located. As soon as the membrane was formed, there were two causes for systemic poisoning: First, the inhalation of the original poison; second, from the maceration of the mucous membrane and absorption. The entire character of the disease was changed according to the seat and extent of the membranous deposit. As an objection to the belief that the two diseases were identical, it had been urged that there was a very marked clinical difference between croup and septic diphtheria. Dr. Jacobi believed that there was a like difference in the clinical manifestations of cases of scarlet fever. We had different types of malarial fever, etc., and why not differences in the clinical histories of cases of diphtheria? There were cases of the latter disease in which no paralysis occurred and kidney lesions were not developed. Such symptoms were not a necessity to the presence of every individual case of diphtheria any more than to the presence of what is known as pseudo-membranous croup. At all events it was unscientific to classify according to clinical symptoms and not to anatomical and histo-

logical differences. Those who distinguished between "pseudo-membranous croup" and diphtheritic laryngitis, were begging the question. They postulated differences as essential, which were but casual and clinical.

DR. J. LEWIS SMITH favored the duality of these two forms of laryngitis, and based his conclusions upon the following considerations:

*First:* The cause. Croup is due to the ordinary cause of inflammation, namely, "taking cold," and is therefore universal (Steiner and others). The cause of diphtheria is a subtle poison.

*Second:* With regard to anatomical characters. Upon that point Dr. Smith remarked that he did not believe it possible to diagnose membranous croup, at the bedside, from diphtheritic laryngitis, in a locality where diphtheria prevailed. It was his opinion that there were cases of diphtheritic laryngitis in which there was no pseudo-membrane upon the fauces and but little tumefaction at the angles of the jaw. Some of those cases would be called croup; but the records had shown that persons exposed to such patients were often seized with the usual form of diphtheria, and without any other exposure. As evidence upon the anatomical characters of croup, the views of Rokitsky were quoted, because he had had the opportunity of studying the disease in a locality where diphtheria had not prevailed. Allusion was also made to the views of Rindfleisch and others, and the following conclusions given:

1. Any mucous surface might be the seat of croupous inflammation; but the most common location was the air-passages, and it occurred most frequently in childhood.

2. Croupous membrane consisted of altered epithelial cells held together by a protein substance. The exact chemical characters of the changes which occurred in the epithelial cells had not been ascertained. No chemical tests were known which would detect the qualitative difference, if any existed, between the exudations of diphtheria and croup.

3. The laryngitis of croup, as compared with diphtheria, appeared to be more superficial. We have seen from Rokitsky's statement, that the croupous exudation never penetrates the mucous membrane underneath. On the other hand, in three instances, recently, competent microscopists had examined, for Dr. Smith, the exudation in the larynx, in cases of diphtheritic laryngitis, and in all, the exudation penetrated and was blended with the mucous membrane, while in the trachea it was entirely distinct from the mucous surface.

4. Croup was a transient inflammation, its cause operating only for a brief period. Therefore the pseudo-membrane of croup is less likely to be reproduced than that of diphtheritic laryngitis. Rindfleisch says it never is reproduced, and we all know how quickly that of diphtheria is restored.

Mention was made of another anatomical fact, namely, disease of the kidney. In several cases of diphtheritic laryngitis he had found albuminuria from nephritis. In croup the urine was sometimes found to be albuminous—but albuminous, it was thought, only in those cases in which there was a passive congestion of internal organs, due to impeded respiration. The following clinical facts were noted as having led the doctor to embrace the doctrine of duality with reference to these diseases:

1. Croup was a local malady. Inflammatory diseases from non-specific causes are local, and why not croup? Systemic infection resulted only from the entrance or retention of some noxious principle, and there is no evidence that this occurs in croup.

2. In croup there was a single tract of continuous

inflammatory exudation. If it was a systemic disease, we should expect to find, in some instances at least, the characteristic exudation upon some other surface than that of the air-passages.

3. The depression present in cases of diphtheria was lacking in croup. If croup was a constitutional disease, there should be symptoms of blood change after the malady had ceased.

4. Tolerance of depressing remedies indicated the local nature of croup.

On the other hand Dr. Smith believed that diphtheria was constitutional at the very commencement, and that the local inflammations which occurred were simply manifestations of a blood disease. His opinion was based upon the following data:

1. The long incubative period in certain instances. A week might elapse, after exposure, before symptoms of diphtheria commenced.

2. Severe constitutional symptoms, lasting for a shorter or longer period—perhaps for twelve hours—might be present before the appearance of the usual inflammation.

3. Early and repeated local treatment of the inflammation did not prevent the occurrence of symptoms of blood poisoning in all cases of severe type. Local treatment was to be used to prevent septic poisoning, but it did not prevent diphtheritic systemic poisoning.

4. The state of the kidneys afforded evidence of a constitutional malady. In certain cases of diphtheria the urine was albuminous, as soon as any of it could be obtained. That was regarded as a strong argument in favor of diphtheria being primarily a constitutional disease, whether the local manifestation was a pharyngitis or laryngitis, for the poison penetrates the system before it reaches the kidneys.

5. Diphtheria occurred at a very early age. True croup, it was believed, did not occur under the age of six or eight months—for the most part not under eighteen months; and it did not occur, as a rule, after sixteen years of age.

The question of contagiousness was regarded as important, and the fact that one was contagious and the other not was held to be strong evidence that the two affections were distinct.

Dr. Smith derived an argument from the records of the Board of Health of the city of New York in favor of the opinion that croup and diphtheria were two distinct diseases.

The statistics, during the long period from 1804, when the tables were first prepared, up to 1850, furnished no recorded death from diphtheria; but deaths from croup were recorded very frequently, being not less than sixty annually—the number in 1817—and averaging one hundred and forty-seven annually during the forty-six years. Now if the croup of that period was identical with diphtheria, as diphtheria was not recognized, would there not have been a larger number of deaths annually from pseudo-membranous pharyngitis than from croup, since, in a majority of those who died from diphtheria, pharyngitis was the prominent inflammation? But the fact was, that during those forty-six years all the inflammatory maladies of the throat were grouped under one head, and their aggregate was only about one-fifth as large as the number of fatal cases of croup. Did not that fact afford a strong argument in support of the belief that the croup of that period was not a form of diphtheria, but was distinct from that malady?

The discussion was continued by Drs. Billington, Peters, Post, Jacobi, and Smith.

The same subject will be discussed at the next stated meeting of the Academy.

ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from February 4 to 10, 1877.*

RANDOLPH, J. F., Surgeon. Assigned to duty in Military Division of the Atlantic. S. O. 29, A. G. O., Feb. 8, 1877.

GREENLEAF, C. R., Surgeon. Relieved from duty in Dept. of the South and assigned to duty in Dept. of the Gulf. S. O. 28, A. G. O., Feb. 7, 1877.

WATERS, W. E., Asst. Surgeon. Assigned to temporary duty at Fort Columbus, N. Y. H. S. O. 29, C. S., A. G. O.

GARDNER, W. H., Asst. Surgeon. Assigned to duty in Dept. of the South. S. O. 29, C. S., A. G. O.

BUCHANAN, W. F., Asst. Surgeon. Assigned to duty in Dept. of the South. S. O. 29, C. S., A. G. O.

BENTLEY, E., Asst. Surgeon. Assigned to duty in Dept. of the Gulf. S. O. 29, C. S., A. G. O.

VICKERY, R. S., Asst. Surgeon. Relieved from duty in Dept. of the Gulf, and assigned to duty in Mil. Div. of the Atlantic. S. O. 29, C. S., A. G. O.

WILSON, W. J., Asst. Surgeon. Assigned to duty at Fort Craig, New Mexico. S. O. 22, Dept. of the Missouri, Feb. 3, 1877.

SKINNER, J. O., Asst. Surgeon. Granted leave of absence for one month. S. O. 28, Dept. of the South, Feb. 6, 1877.

DEATH OF SIR WILLIAM FERGUSSON, BART.—Sir William Fergusson, President of the Royal College of Surgeons and Sergeant-Surgeon to the Queen, died Feb. 10, in London, at the age of 69. He was born at Prestonpans, East Lothian, Scotland, March 20, 1808. He received his early education at Lochmaben Grammar School, and continued his studies in the High School and University of Edinburgh. He began his professional studies at the age of eighteen, under the noted anatomists Drs. Knox and Turner, the latter of whom occupied the chair of Surgery in the Royal College of Surgeons, Edinburgh. His progress was so rapid that in less than a year he became the confidential assistant of his learned and skillful preceptors in the preparation of their "subjects." He continued his intimate professional relations with Dr. Knox for nine years, and thus enjoyed opportunities for pursuing his favorite study—anatomy—rarely presented to the medical students of his day. He became a licentiate of the Royal College of Surgeons in 1828, and a Fellow of that corporation the year following, and in 1831 he began to lecture on the principles and practice of surgery. In 1836 he was appointed Assistant Sur-

geon to the Royal Infirmary, and was chosen a Fellow of the Royal Society of Edinburgh in 1839. A year later he removed to London, where he was made Professor of Surgery in King's College and Surgeon to King's College Hospital. He was chosen a member of the Council of the Royal College of Surgeons, London, and for some time was Professor of Surgery and Human Anatomy in that institution. For five years he was Examiner in Surgery at the University of London, and was chosen member of most of the medical and scientific societies of Great Britain, being a Fellow of the Royal Society of Great Britain, Vice-President of the Royal Medico-Chirurgical Society, a Fellow of the Obstetrical Society, and President of the Pathological Society. At the time of his death he was President of the Royal College of Surgeons. He was also Consulting Surgeon to the Hospital for Consumption and Diseases of the Chest, to the British Home for Incurables, to the Hospital for Diseases of the Throat, to the Scottish Hospital, to the Calceonian Asylum, and Honorary Surgeon to the St. George's Hospital. He was also Surgeon Extraordinary to the Queen. Among his works he has left *A System of Practical Surgery*, and *Progress of Anatomy and Surgery in the Nineteenth Century*, which was published in 1867; besides special papers on Cleft Palate, Lithotomy, Lithotrity, Excision of Joints, Aneurism, and other subjects.

SMALL-POX IN LONDON.—The continued prevalence of small-pox in London has invited attention to all questions connected with its prevention and cure. Revaccination is urged, and every precaution is taken by the Government to prevent the spread of the disease, and the establishment of special hospitals is strenuously advocated. The Registrar General has requested practitioners to state in their certificates of small pox cases if the subject has been vaccinated, and at what age. The test which will be recognized as trustworthy is the presence of an undoubted scar in the usual situation. A majority of the public is reported as objecting to revaccination, on account of the danger of syphilitic contamination, and efforts are being made to introduce bovine virus.

UNIVERSITY OF VERMONT, MEDICAL DEPARTMENT, AT BURLINGTON, VERMONT.—Miss Fletcher, of Burlington, has recently donated \$75,000 for the building of a hospital, and \$100,000 for the endowment of the same. The hospital will be the first institution of the kind in that State. This will give an opportunity for clinical study in connection with the College course, not enjoyed by any similar institution outside of our large cities.

DR. D. TILDEN BROWN.—We regret to learn that the health of Dr. Tilden Brown, the accomplished Medical Superintendent of the Bloomingdale Asylum, is in such a precarious state as to necessitate his absence abroad for an indefinite period.

INFECTIOUS DISEASES.—We observe that the recent order of the Health Board, regarding the publication, with the funeral notices, of infectious diseases of which patients have died, is quite generally observed. No measures have as yet been taken to prevent the bodies of children, dead with scarlet fever, etc., from transportation in hearses instead of ordinary coaches.

COLLEGE COMMENCEMENTS.—The Commencement of the Medical Department of the University of the City of New York, will take place on the evening of the twentieth, at the Academy of Music; and that of the Bellevue Hospital Medical College at the same place, on the afternoon of the twenty-first.

## Original Lectures.

### EXAMINATION FOR LIFE INSURANCE.

By WILLIAM DETMOLD, M.D.,

EMERITUS PROFESSOR OF CLINICAL AND MILITARY SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK CITY.

(Phonographically reported for THE MEDICAL RECORD.)

#### LECTURE III.

GENTLEMEN:—In the previous lectures we have spoken briefly of general principles which should guide the medical examiner in making his examinations for life insurance. We come now to the examination of the applicant in detail. Of course, an impression has been made by your general survey, but such general impression is sustained or overthrown by details, and the experienced man takes in the whole. We will begin with

#### THE HEAD.

A man comes to you with very thin dry hair, which looks moth-eaten, and almost all the hairs are split at their ends; that does not show a vigorous constitution. A bald head and white hair are perfectly unobjectionable if they come in years; but if they come prematurely, if a person says he is thirty years of age and has a bald head and white hair, there is some sign of early decay. These things are brought about either in consequence of want of vital power or they may be the result of excesses. Therefore, in their time they are all very respectable, but before their time they are not desirable. If there is a family predisposition to gray hair early in life, and the family history shows that the members have been long-lived, the fact of having gray hair is not objectionable. You will then examine the *scalp*. Determine whether there are any adherent scars. Such scars will result from ulceration and they are mostly of a syphilitic character. They may result from injuries. Adherent scars from syphilis show that the system has been affected by the poison; adherent scars from injuries lead to the suspicion that the inner table of the skull has been injured, and that subsequent trouble may be developed in the way of epilepsy. You will occasionally find gummatous swellings upon the scalp; not very prominent, rather diffused, which give a slight sense of fluctuation, and are painful. Such swellings belong to the lesions of secondary syphilis.

You will next look at

#### THE EYES.

A heavy, dull eye, without vivacity, is not prepossessing, and shows a sluggish constitution, unless the person is accustomed to wear spectacles. If a person habitually wears glasses, and then takes them off, it will be found that the eye has no lustre; its mobility and vivacity are lost, for the very simple reason that while using spectacles the person always looks through a focus. That focus corresponds with the focus of the eye in such a manner as to make vision distinct, and necessitates the turning of the head if the person wishes to look to either side, and the eye loses its motion and brilliancy.

There are certain defects about the eye which are to be noted. Fatty degeneration at the upper edge of the cornea, the *arcus senilis*, if present in early age, indicates a tendency to fatty degeneration of internal organs, especially of the heart and kidneys. If present in old people, it is not objectionable, but developed early in life it should reject the applicant. The

differential diagnosis between *arcus senilis* and other affections I must suppose is understood.

I do not think that cataract should influence the application unfavorably, but amaurosis and staphyloema I should regard as objectionable. Further, you should distinguish between cataract and plastic deposit in the pupil. Cataract runs in families and does not prevent the person from reaching old age; but the plastic deposit, which in many cases so closely resembles it, is almost always the result of syphilis, and is objectionable.

Complete blindness in both eyes should exclude the applicant. It is often due to some central lesion, and besides, exposes the person to innumerable accidents.

You should next inspect

#### THE EARS.

If an offensive discharge issues from the ears, the case should be examined especially with reference to caries. If any little pieces of bone have appeared, I think I should decline the risk, for, from very slight causes, the inflammatory process may be transferred to deeper parts, and terminate life. Perforation of the tympanum with such offensive discharge is objectionable. Simple difficulty in hearing is not at all objectionable; it runs in families, is hereditary, but it does not shorten life. Absolute deafness should exclude the applicant because it is too frequently the result of central lesion. Deaf-mutism is objectionable on account of liability to accidents, and is frequently associated with scrofulous diathesis.

You will then look at

#### THE NOSE.

If you observe that the nose has become depressed, inquire as to how it was caused. If it has been done by injury, the fact of its existence does not shorten life; but if in consequence of syphilis, scrofula, or diphtheritic ulceration, it may render the applicant objectionable. If there is a fetid discharge from the nose, you should inquire whether any pieces of bone have appeared, and if so, it is an objectionable application. Simple mucous polypus of the nose is of no consequence in this connection, because it does not interfere with long life. But if there is a polypus which has invaded the antrum it is objectionable. Polypus of the antrum, when it pushes downwards the hard palate and perhaps raises the floor of the orbit, is decidedly objectionable, because it is very apt to become malignant; or, if not malignant, will necessitate an operation which may endanger life.

When I see a network of blood-vessels upon the nose of a person in middle life, I always regard them with suspicion. I do not refer to the delicate blue veins which constitute an element of female beauty, but congeries of vessels which look as if injected with red; they are usually the forerunners of apoplexy. Epistaxis, occurring in young individuals, is not of special consequence, but occurring in elderly persons it is decidedly objectionable, inasmuch as it is almost invariably a forerunner of apoplexy. Occurring in persons somewhat advanced in years, it is usually difficult of arrest, and depends upon changes which have taken place in the smaller blood-vessels. The same changes are present in the blood-vessels of the brain, and I have rarely seen a case of epistaxis in old persons who have not subsequently suffered from an attack of apoplexy.

You will next look into

#### THE MOUTH,

and first at the *tongue*. If the tongue is ragged upon its edges, you may be quite certain that the applicant

is subject to epileptic fits, for during those fits it is frequently wounded by getting between the teeth. He conceals the epilepsy, but the ragged edge is almost invariably found where it has been present. There may be evidences of old ulcerations in the *throat*, such as deficiency of the soft palate, etc., and, if the result of syphilis, as they are very liable to be, you must judge as to what extent the specific disease has affected the general constitution. As a rule, however, there is no objection to such applicants; but if there is a very great deficiency, either in the soft or hard parts, in consequence of ulceration, it is objectionable. I think that even congenital cleft-palate should reject the applicant for life insurance. If, in a young person, the teeth are found to be decaying, the fact perhaps has no special significance. But decaying teeth in the mouth of a person, say thirty-five years of age, may have considerable significance, especially if associated with an exposure of the alveolar process from absorption of the gums. The fact may then indicate premature decay, and although the bad teeth of themselves should not disqualify the applicant, yet, taken in connection with other conditions, may afford valuable suggestions.

#### THE FACE.

Suppose the applicant shows some signs or remnant of facial paralysis, the mouth being drawn to one side, you must ascertain the cause; if it is the ordinary facial paralysis which has its origin in the peripheral or local nerves, it is not objectionable; but you should examine whether the person has lost power in the hand of the same side; if so, the cause has been central, and the applicant must be rejected.

You will next inspect

#### THE NECK.

A short, thick neck indicates liability to apoplexy. See whether there are any scars from old ulcerations. If there are, and they are from scrofula, they are not of much account, but if there are present any glandular swellings, they are decidedly objectionable; for, such glandular affection will extend downward into the mediastinum, and afterwards lead to phthisis. Examine the post-cervical glands; if they are enlarged, it is an indication of secondary syphilis. See whether the person has had a seton in his neck; if the marks are remaining, determine why the seton was used. The same may be said with regard to the scars left from cupping, and it may be remarked at this point that scars from cupping, or setons, or venesection upon any part of the body, should at once excite your suspicion, for it is quite probable that the person has suffered from some grave disease. Make thorough inquiry into the history of the case when you see the back, or arms, or any part of the body of the applicant covered with scars from leeching, cupping or bleeding, for those things are not done for amusement. You may now look at

#### THE BACK.

See whether there is any positive emvature of the spine, either angular or lateral. Angular curvature always excludes the application; lateral curvature should not always exclude it, and should do so only when the curvature is sufficient to disturb the action of the heart. When the displacement of the heart, from lateral curvature, is sufficient to disturb its action, it is sufficient cause for the rejection of the applicant. There is one form of curvature of the back which is harmless. In all large cities—whether the same holds good in the country, I am not

certain—a straight back in young girls is exceptional. In by far the greater proportion, the right shoulder is a little higher than the left, in consequence of a very light bend in the dorsal vertebrae. If there is no more curvature than this, the case is not objectionable. There are certain deviations from the straight line brought on by occupation. For example, among carpenters, the right shoulder is considerably higher than the left, but such a deviation has no special significance. We come now to

#### THE THORAX.

The thorax includes most important organs, and diseases of those organs are most injurious to the insurance company. In the first place, the thorax of the applicant for life insurance should be well formed. We have already studied a table showing the proportion which should exist between the circumference of the chest, and the height and weight of the man. Notice to what extent the chest expands. In health, the ordinary expansion is one inch, and the chest should be capable of being expanded three inches with a forced inspiration. If it does not do that there is something wrong. You may next take the dimensions of the thorax. The circumference of the chest should be double the distance from the tip of one shoulder to the other. The circumference of the chest should be four times the antero-posterior measurement made at the lower part of the sternum. The distance between the nipples and the anterior posterior measurement are equal, hence the circumference of the thorax is four times the distance between the nipples. There should be no sinking of the chest wall under the clavicles, and the expansion should be nearly equal upon both sides; the right side normally expanding a little more than the left. The respiratory capacity in a well developed man, five feet eight inches in height, should be 230 cubic inches, with forced inspiration, although, in the ordinary inspiration and expiration, rarely more than twenty cubic inches of air are changed. The capacity upon forced inspiration should be 230 cubic inches, and any great deviation from that is decidedly objectionable; if there is a deviation of sixteen per centum, it should reject the applicant. There is either want of vitality or some organic trouble to account for it.

Now, the capacity of the lungs in a healthy man, five feet and eight inches in height, being 230 cubic inches, it should increase eight inches for the addition of every inch; so that a man five feet and nine inches in height, should have a respiratory capacity of 238 cubic inches, and any great deviation from such proportion is objectionable. The proportion holds good from five to six feet. In females the capacity of the lungs is considerably less. The number of respirations to the minute, without excitement, is about seventeen, and should bear a proportion to the pulse of one to four or five.

After having taken this general view you may examine the thorax with reference to resonance. The most important question to be decided is, whether the resonance is perfectly good just above and below the clavicles, for that is the predilection-seat of tubercular deposit. If there is any deviation from the normal upon either side, reject the applicant. There may be a slight diminution of resonance at the lower part of the thorax, perhaps as the result of a slight attack of pleurisy or pneumonia, which I do not think of itself will shorten life, yet, as a rule, I would reject the application. The person examined may live a long life, but when 1,000 such persons are taken, they will not give a good average. If the condition of itself does

not exercise an unfavorable influence, it may indirectly diminish the power of resistance so as to render the person more liable to death from other diseases. Your opinion, although it is given upon the individual, may be entirely wrong with reference to that particular person; and you may reject a man who lives for years. Why? Because he is such a poor invalid, and yet he may outlive the healthiest man. But suppose the insurance company takes such lives? One such person might live for a long time, but the average, upon a number of such cases, would be such as no insurance company could stand.

It is not my purpose to enter into the study of minute diagnosis of diseases of the lungs, for the medical examiner has only to be familiar with the normal sounds, and if the normal vesicular respiration is not heard, or if there is prolonged expiration, the application is objectionable. If, afterwards, you wish to determine what has produced that deviation from the normal condition, you can do so at your leisure. The same thing is true of the heart. Make yourself familiar with the normal sounds, for any deviation from health is objectionable. It matters not whether the deviation be in the form of friction, aortic, mitral, diastolic, systolic, or presystolic murmur; you do not wish to accept any abnormal sound.

We next come to

#### THE ABDOMEN.

Here you will be obliged to determine whether there is any increase or diminution in the size of the liver, spleen, and other organs, and whether there are present any abnormal growths. Determine whether hernia is present. Statistics show that hernia is present in one out of every fifteen adults. A simple reducible hernia is not objectionable, providing the person pledges himself to wear a truss. An irreducible hernia is decidedly objectionable. I think that an umbilical hernia in the adult, especially in fat subjects, should be declined. Almost all the operations for strangulated umbilical hernia prove fatal; recovery is exceptional. Furthermore, the trusses which afford satisfactory treatment for this form of hernia are difficult to obtain. I should object still more strenuously to a ventral hernia.

If there are any scars or glandular swellings in the groin, they suggest the probability of buboes; at all events, should lead to careful inquiry with reference to constitutional diseases.

You should determine whether albumen or sugar is present in the urine. If there is any cause for suspicion—if there is any evidence which would lead you to suspect that the urine contains either albumen or sugar—do not trust any one interested with obtaining the urine, and making the necessary examination. You may ask the applicant concerning his urine and he will tell you it is all right, that he has had it examined, and that it contains no albumen. He gives you a sample; you examine it, and find that it contains no albumen, but it may be his wife's urine. The reason he has brought the urine for examination is because he knows well that his own contains albumen, and he has therefore substituted for it that of his wife or confidential neighbor. Be certain that the urine to be examined comes from the person making application for life insurance.

We will now glance at

#### THE EXTREMITIES.

You will first look at the muscular development. Tremulous hands either show a very nervous temperament or are the evidence of chronic alcoholism.

Determine whether there are present any marks of cupping, leeching, or general bloodletting. Determine whether the joints of the fingers and toes are enlarged from rheumatic or gouty deposits. Examine the nails; if they are convex in the longitudinal axis, it is decidedly objectionable, and especially so if the extremities of the fingers are also bulged. These signs are indicative of central trouble. If all the nails are malformed, discolored, and covered with thick ridges, it is very apt to be a sign of secondary syphilis. On examination of the feet, you are to determine whether there is any œdema; see whether there is any œdema about the ankles; if so, it must be accounted for. It may indicate impairment of circulation; a general weakened condition of the system; perhaps in consequence of recent illness; and it may be evidence of central disease affecting the kidneys. Decided œdema over the anterior surface of the tibia indicates secondary syphilis. Any enlargement of the knee-joint is decidedly objectionable. Very large varicose veins, especially if they extend above the knee, are objectionable.

The testicles, I think, should be healthy; any hard swelling of the testicle itself is objectionable, although a slight enlargement of the epididymis may not be. A little varicocele is not objectionable for life insurance. Any indication of urethral or rectal stricture is decidedly objectionable. Anything which interferes with the free discharge of the urine or feces is decidedly objectionable.

With these remarks, gentlemen, I am necessitated to bring my lectures to a close. I have endeavored to direct your attention to the importance of life insurance examination, and to point out wherein it differs from other examinations you may be called upon to make while in your professional pursuits. I also think, if you will follow out the suggestions which have been made, that you will not have occasion to regret the time you have given me during these lectures, which were intended to be rather suggestive than exhaustive.

## Original Communications.

### A NEW RECTAL DILATOR AND EXPLORER, WITH TWO CASES ILLUSTRATING THEIR APPLICATION.

By PHILIP S. WALES, M.D.,

MEDICAL INSPECTOR U. S. NAVY.

THE treatment of stricture of the rectum is always tedious, painful and difficult, and in an increasing proportion to its distance from the anus. The malignant forms are uniformly fatal, and it is only in the non-malignant varieties that a successful issue may be secured by surgical measures. The ordinary appliances employed in the latter class of cases have not been altogether satisfactory, particularly in those instances in which the obstruction is seated high up in the bowel, and beyond the reach of the finger. Having recently had two cases of this latter sort, in one of which particularly, the practical difficulties culminated from the height of the stricture, I had recourse to certain mechanical contrivances with the most gratifying results. I shall first relate, as succinctly as possible, the cases, and then describe the instruments with which they were treated.

CASE I.—The Admiral of the Navy consulted me, Nov. 23, 1875. He stated that he had been ill for

four or five years; had lost much flesh; his mental powers—especially memory—had become impaired; that he was gloomy and foreboding; the slightest exertion exhausted him so that he rarely took exercise. The bowels had been obstinately constipated, requiring numerous and daily injections, in connection with cathartic medicines, to solicit a movement, and then but a trifling amount could be passed. His appetite was poor and capricious, and his sleep was disturbed and unrefreshing. The abdomen was distended and often tender, and one of the most annoying symptoms was frequent and painful contractions of the anterior crural muscles. His skin had assumed a decidedly yellow tinge, and his countenance wore a haggard and very painful expression.

He said he had consulted many physicians, and had had his case made out to be cancer of the bowels, disease of the kidneys, liver, spleen, and stomach; in fact, all the chylo-poietic viscera had been, from time to time, charged with occasioning all the trouble; hence the variety in the plans of relief.

He certainly presented, when he came under my care, the appearance of a person suffering from some chronic organic disease, and had I been asked to diagnose his case from mere inspection, I would most likely have guessed malignant disease located in some place yet to be discovered; but the history of the case, the time that had elapsed since it began, and the retention yet of something of a vigorous frame, caused some mis-giving in this direction. The finger detected no obstruction in the rectum; a ten-inch endoscopic tube, thoroughly illuminated, revealed a more than usual narrow but otherwise healthy bowel; abdominal palpation showed some degree of colonic impaction; and percussion, great distention of this portion of the intestine. Could there be a stricture between the narrowed bowel below and the expanded colon above? An explorer was introduced and a stricture found thirteen inches from the anus, through which a flexible bougie, one quarter of an inch in diameter, could just be made to pass after a tedious trial.

The case was now a plain one as far as the diagnosis was concerned, and for its proper treatment there was only lacking an efficient dilating apparatus. The old-fashioned bougies, which I had frequently applied before in low-down stricture, were tried with but little success. They were too short, inflexible and painful on introduction. I also suspected that the colon, so long dilated, had undergone change in consistence and needed to be gingerly handled. It then occurred to me that if india-rubber dilators could be gotten, the work might be done safely and efficiently. Search was made in the large commercial cities, but nothing of the sort was procurable; finally drawings were prepared and the needed instruments were manufactured at a large rubber factory in New York. Although not exactly perfect, the labor of dilating was begun, and after persisting in the treatment for five months, figured stools passed, and the Admiral regained his pristine vigor of mind and body.

Case II.—Lieutenant-Commander B—consulted me March 7, 1876. The following is a history of his case, condensed from a written communication: "During the years 1868 and 1869 I suffered very much with constipation; I had a broken stool every morning, immediately after breakfast, and another about an hour later, with distress between them. The stools were slimy and accompanied with crepitation, being passed without straining, as if forced out by the wind. My general health was good, although at times I was

troubled with a feeling of fulness in my head. I was on shore duty at this time. Have always suffered a good deal with constipation at sea, but up to this time had no trouble while ashore. During my last cruise in 1869 and 1870 I suffered so much with constipation, that I hardly ever had a movement, when at sea, without the aid of medicine.

In August, 1870, I caught cold, which produced gastric catarrh. I had, after this, several very large and "fermented" stools during the day, accompanied with great burning in the lower intestine, and general exhaustion. This trouble lasted about three weeks. In October, 1870, I went to Mexico on a surveying expedition and was some five months in the mountains. I was hard at work all the while, on horseback every day, and felt very well most of the time, although I had several attacks of diarrhoea with mucous discharges, and great pain near the rectum just before passing a stool. My strength kept up, and I was very well on my return to the United States in May, 1871, but about a week later my nervous system seemed to give out all at once. While in Mexico I had but one stool a day, immediately after breakfast; I now had several, all broken and accompanied by mucus. I felt distressed during the morning until all the fecal matter had been passed. I was excessively nervous; although I had been a smoker for many years, I could not touch a cigar. The least excitement put me in a tremble all over. I consulted a physician, who said that my system was full of malaria. Later I had a return of the "fermented" stools, when I was recommended a diet of rice and milk, which I continued for several months, the "fermented" stools disappearing in a few weeks. At last I became so weak that I could scarcely walk. I then had electricity applied to my stomach, and changed to a more nourishing diet. In 1872 I spent four months travelling in Europe, was very miserable, and could bear very little fatigue or excitement. I generally had two stools in the morning, preceded by intense pain in the lower bowel. I was taken sick at Venice with a violent diarrhoea, which lasted ten days, having a small passage of clear mucus every hour or two, for two or three days, preceded by intense pain in the bowels. The doctor whom I called in recommended a diet of beef tea, arrow-root and champagne, which I kept up for three months, until my return to the United States. I spent fifteen days at a magnetic spring in Michigan, which seemed to restore my nervous system in a great degree. In 1872 I noticed that my stools were composed of balls about one-half of an inch in diameter, and three or four in number during the morning; besides this sort of discharges, the least excitement or passing into a cold or damp room caused an evacuation of about a tablespoonful of semi-transparent mucus.

The balls passed gradually became smaller and at last the stools consisted of a flat or three-cornered strip, about six or seven inches long, of good color, but coated with slime. I consulted with many physicians, most of whom said that I was notional, having so many symptoms. I was finally obliged to abandon my professional duties. My mind was much confused at times, I had intense headaches, loss of memory, and great dread of any difficulties or excitement. In the spring of 1875, I felt satisfied that there must be some stoppage or obstruction in the intestine, and forthwith consulted an eminent physician. He made an examination with his finger and stated that there was no stricture; copaiba was prescribed, but I had to give it up in a few days, as it affected my kidneys, and gave me severe pain in my back. I had many functional difficulties, my eyes became very sensitive to light, and

there was a continual burning sensation in the bowels, accompanied with great depression of spirits, fullness of the head, and a sensation of weight on the top of it, a continual sense of fullness and burning in the back, as if there were veins starting from the lower part of the spine and branching out towards the shoulders, and distended with hot, burning blood. This feeling in my back was so great that I could not lie on my back or lean against a chair. I was obliged to pass my urine every two or three hours, and have been afflicted with seminal emissions throughout my troubles. At present, January 1, I am free from all the foregoing distressing symptoms, and have figured discharges of good size."

In this case the stricture was found to be located seven inches up the rectum, and has been sufficiently dilated to permit the passage of an instrument three-quarters of an inch in diameter. The dilators used in the cases above related were manufactured, as stated, out of pure rubber, with a canal running the whole length, and gradually increasing in size by an eighth, from a quarter of an inch to an inch in diameter. Each dilator is fitted with a gum sheath of corresponding dimensions. In order to secure the most perfect construction, a model was submitted to Mr. J. H. Gemrig, of Philadelphia, who has, with his well known skill, made an admirable set of eight dilators. The accompanying cut, Fig. 1, will furnish a good

FIGS. 3, 2, 1.

FIG. 1.—The Dilator. FIGS. 2, 3.—The Explorer, dilated and undilated.

idea of them. It represents one of the dilators, with its sheath undilated, and connected with the syringe by which the sheath can be distended with water. The sheath may also be inflated by Politzer's air-bag, or other suitable contrivance. The points of the dilators may be terminated spherically, or taken for an inch and a half, or two inches conically, the latter form, on the whole, being more easily introduced. The sheathes made by Gemrig do not burst under ordinary pressure, as those did I employed at first; besides the loss of the sheath, no damage is otherwise done. A low thud and a peculiar sensation felt by the patient at the moment announce the accident and

alarm nervous subjects. The whole length of the sheath, both inside and outside the bowel, or any portion of it, may be filled with water; in the latter case a thread of silk is to be twisted around the dilator at any point that it may be desirable to limit the distention. Indeed, the sheath might be made in one piece, with the central portion for one-half or one-third of its length—a modification which I shall test at an early period. Ordinarily, however, I believe it will be advantageous to distend the entire bowel below the stricture at the same time that the stricture is being acted upon, as I have several times observed a general narrowing below the obstruction, which, I presume, is owing in part to the fact that the bowel is bereft of the habitual distention from the daily passage of moulded fecal matter in the normal condition.

The method of introducing the dilator is simple. I prefer placing the patient, reclining on his left side, upon an ordinary operating-table, the thighs flexed and the buttocks just overhanging the lower edge. The operator may then comfortably seat himself during his manipulations—an advantage of no ordinary character, if they are to be at all prolonged. The smallest-sized instrument is smeared with grease, and its point inserted into the anus and gently pushed onward in the following manner. The right hand grasps the dilator close to the anus, and the whole perineum is to be pressed upwards, which will advance the point of the instrument; the left hand now steadies it, while the right is slid downwards for a lower hold, the perineum of course settles with it; the dilator is again pushed forward in the same manner until the obstruction is passed. I have occasionally found that this may be greatly facilitated by sinking the fingers of the left hand deep into the left iliac region, and drawing upwards, as though an effort was being made, so to speak, to stretch out the sigmoid flexure, while pressure is maintained at the same time upon the dilator in the manner described. Another practical point of prime importance is to employ an abundant stream of water, projecting it through the conduit of the instrument as warm as can be comfortably borne, whenever its point is arrested from any cause. The water flowing from the distal aperture will distend the bowel, efface its folds, and break down any hardened faeces that may exist, obstructing the ascent of the dilator. While the operator is engaged with the dilator, an assistant may manage the syringe and throw in the water in such quantities as may be needed. It must be borne in mind, however, that no great volume should be used at once, otherwise the bowel will be excited to energetic contraction, and compel the dilator to be withdrawn before it has been properly lodged. In preliminary trials, the dilator may be permitted to remain two or three minutes, and afterwards, when greater tolerance is established, a longer stay may be allowed. I rarely exceed half an hour in any case, even when the patient makes no complaint of irritation or pain. After several introductions of one size of the dilators, perhaps seven or eight, the next largest may be taken, and so on until the stricture has been sufficiently expanded. The application of the instrument may be repeated twice or thrice a week, according to circumstances, such as the irritability of the rectum, temperament of the individual, and intercurrent attacks of diarrhoea or other trouble. Twice a week, in my experience, suffices in most cases of rectal catheterism. A fortunate issue, if attainable, can only be brought about by patient and prolonged treatment. Rudeness or violence, inflicted with a view of hastening the case, can effect nothing but harm, and may

jeopardize the life of the patient. If the instruments be hastily thrust in, the bowels may be perforated, especially in those cases in which inflammatory softening or ulceration exists; or, if they be too large, the rectal mucous membrane may be ruptured, giving rise to smart hemorrhage, as happened in one of my early cases; or the entire wall of the bowel may be ruptured into the peritoneum—an accident that is pretty sure to be followed by peritonitis, with all of its attendant dangers.

These funest sequences are infinitely less liable to follow the use of pure india-rubber dilators than that of any other sort; for certainly, *à priori*, nothing could furnish a milder, more equable, and less dangerous force than these, and experience sustains this view.

That the pressure possessing these merits is all-sufficient to effect the result desired, is shown by the cases cited above; indeed, the maximum distention obtainable by the dilator cannot, even were it safe to exercise it, be supported by any person not anesthetized, and hence the unnecessaryness, in the majority of cases, of the numerous forms of those dilators constructed with a view of gaining great mechanical power. Possibly in exceptional instances, they may be found applicable, and any severe suffering may be easily eliminated by chloroform; but the only safe plan in rectal instrumentation is to proceed with the patient in the full possession of his consciousness, so as to secure the assistance of his sensibility in guiding the hand while managing the dilator. I have not yet encountered a single stricture case that did not suffer very much, both in the introduction and the expansion of these contrivances; and in constriction situated high up in the bowel they are altogether inadequate.

I have now introduced these rubber instruments into the intestine several hundred times, without discovering any major objection or defect. Some of my friends have, however, expressed a suspicion that, being so soft and flexible, they are likely to deceive by doubling in the intestine, instead of slipping along the mucous membrane. This is, of course, possible, but I have not as yet seen them perform the whimsical caper of knotting, which occurred in the first case related in this paper, with a flexible tube, such as is ordinarily used in connection with the stomach pump. It was passed eighteen inches into the bowel, and, as I supposed, stretched out its full length. On attempting to withdraw it some resistance was felt, which

FIG. 1.—Knot tied in a rectum tube.

required no little tractile force to overcome. The difficulty was at once apparent; the tube was tied in a single knot, as shown in the appended sketch (Fig.

4), made by the Admiral himself, who has kindly furnished me with it.

I have also been using the dilators in applying ointments, variously medicated with astringent and anodyne substances, in cases of relaxation of the intestinal mucous membrane, prolapse, hemorrhoidal tumors, and other morbid rectal conditions. A slight modification converts the dilator into an irrigator; that is, by having two parallel conduits in it—one for the fluid to pass in, and the other for it to escape externally. The bowel may be thus irrigated quite high up, for I have frequently inserted the instrument twenty-eight inches into the colon. In one case the patient passed every morning one or two large, yeasty stools, mixed with mucus, and followed by much mental depression. A cure was obtained by the injection, three times a week, of a solution of carbolic acid, after internal medication had failed. Much advantage may be realized from the use of warm irrigation in various diseases of the contiguous pelvic and abdominal organs—as cystitis, prostatitis, suppression of urine, and intussusception. The half-inch dilator will furnish a ready tube for introducing alimentary substances into the stomach or rectum. Stricture of the œsophagus, though I have treated no case of this sort with the dilator, yet with my present experience in rectal constriction, I feel pretty sure may be most satisfactorily managed in an analogous manner.

To supply a want long felt of a facile and reliable means of diagnosing intestinal diseases, I have constructed an explorer (Figs. 2 and 3), which has worked admirably in my hands; and some of my friends, who have employed it in cases in which stricture was suspected to be present, have assured me that they regarded the evidence furnished by the instrument as very conclusive. It may be prepared in the following manner: take a dilator, say one-half an inch in diameter, and over its distal extremity draw a hood of thin india rubber two inches long, securing its margin with a fine silken thread. If the rubber is not at hand, a piece of moistened bladder or gold-beater's-skin will answer very well. The instrument thus made ready should be well coated with a stiff grease, like simple cerate, or zinc ointment, which, I find, works better than sweet oil in facilitating its gliding over the mucous membrane, and introduced in the manner I have already described for the dilator, until its point is lodged far above in the descending colon. A syringe is attached to the instrument, and its point expanded into the form of a ball an inch or more in diameter. Gentle traction is now to be made, which will cause the ball filled with water to move slowly down the bowel. If no obstacle is present, the ball will soon emerge from the anus; on the contrary, any obstruction will arrest it above. It may be that spasmodic contraction will have a like effect, but this can be easily distinguished from permanent stricture by keeping up the traction a few moments, until the muscular force of the intestinal walls is exhausted, when the ball will again slip along. I always use hot water, and smear the explorer with belladonna or iodoform ointment, with a view of eliminating this source of error. In cases of organic narrowing, its degree may be determined approximately by maintaining the traction on the explorer, while the water is permitted to flow out in small quantities at a time, until the size of the ball is sufficiently reduced to slip past the constriction; the diameter of the ball, which represents that of the stricture, may be now ascertained by mere inspection. Although, practically, an explorer prepared in this simple manner is quite efficient, yet, to secure an instrument always ready and more

artistic. I am endeavoring to get the point and body made in one piece, with a second conduit running along the stem, and terminating behind the ball, so that a stream of water may be ejected at any moment, should the point catch in the intestinal wall.

## Progress of Medical Science.

**SUDDEN DEATH FROM EMBOLISM.**—Dr. Fitz, of Boston, has collected four cases of sudden death occurring in patients that were under medical observation, and on whom post-mortem examinations showed an obstruction of the circulation in some of the principal vessels. Dr. Fitz believes that such accidents will happen so seldom in the course of any physician's practice—even then causing doubt as to their real nature, that the review of the main facts in these cases will be of interest. While he finds that there are no symptoms that point absolutely to embolism, some are suggestive, and may enable the physician to be tolerably sure of his diagnosis. Unfortunately, treatment in any case offers little hope. In one instance a lady was suffering from a mild attack of typhoid fever, with a slight paroxysmal cough and rushes of blood to the head, with difficulty of respiration and irregular action of the heart. In one of these attacks she died, after an hour's struggle. The cause of death was credited to a primary "embolism of a small branch of the pulmonary artery and its extensions to the heart, by secondary coagulation until it protruded into the main pulmonary artery." In another case, a lady, fifty-two years of age, who had enjoyed robust health, began to suffer from occasional attacks of diarrhoea. She became worse, was seized suddenly one day with dyspnoea, and in two hours died. The immediate cause of death was a thrombus of the primary pulmonary artery, in appearance firm, gray, and laminated. There were no symptoms during life pointing to thrombosis, and there was no evidence of embolism preceding the final attack. In the third case, the patient was a lady, twenty-five years of age, who was delivered of a healthy child by turning, little blood having been lost. A few hours afterwards she had a chill and pain in the left iliac region, and for twenty-four hours after delivery the after-pains were severe. But these unfavorable symptoms gradually disappeared, and convalescence set in. On the 24th day after delivery she moved from her chair to the bed, lay down, and immediately began to breathe with difficulty. Her face began to be livid, her tongue blue, and she tossed about, complaining of intense pain in the epigastrium. Death took place in fifteen minutes. "A soft, reddish-gray thrombus, the size of the forefinger, extended from the right iliac vein into the inferior vena cava for two inches. Thrombi were also found in the right ovarian vein and in the vesical plexus. The tricuspid orifice contained a club-shaped embolus, one and a half inches in length, the larger end being the size of the tip of the forefinger. Both primary pulmonary arteries were plugged with emboli. Where the origin of the trouble could have been in this case is still a question. In two instances there was chronic valvular disease of the heart, thus favoring the production of thrombi, and there was embolism of pulmonary arteries. The main symptom recognized in these cases has been suffocation; and in making a differential diagnosis we have to decide between (1) closure of the greater air-passages, or of a large number of small ones, from without or from within; (2) nervous lesions

affecting respiration and circulation; and (3) obstruction to the pulmonary circulation from emboli. In regard to the first series we may have no great difficulty. In the second we have the symptoms of cerebral anaemia, viz.: pallor, relaxed muscles, disturbed vision and hearing, etc. In case of embolism we have the history of an antecedent thrombus, or some form of heart disease which occurs in association with thrombosis.—*Boston Medical and Surgical Journal*, Jan. 25, 1877.

**CYSTIC BRONCHOCELE WITH METASTATIC DEPOSITS IN THE LUNGS AND BONES.**—Professor Cohnheim, of Breslau, reports an interesting case, which appears to be unique. A feeble woman of thirty-five had been under surgical treatment for suppurative synovitis of the knee and sacro-iliac disease, of which she finally died. At the autopsy it was observed that there were deposits in the lungs and in the femur and lymphatic glands. She had also a bronchocele, the right lobe showing under the microscope only the ordinary follicular appearance, while the left was cystic, and contained gelatinous matter. The deposits in the lungs and bones and lymphatic glands had precisely the same minute structure as the left lobe. The author of the article has found that Eberth reported a similar case in a dog; but with this exception it is the only case known to him in which this form of humor has exhibited metastatic deposits.—*Archiv f. Path. Anat.*, lxxviii., 4, 1876.

**OPEN DRESSING OF WOUNDS.**—In a recent lecture at the Westminster Hospital, Mr. Davy enumerated the excisions and amputations of the past two years—thirty-three in all, including two excisions of the hip, one amputation of the thigh, five Syme's, and two Chopart's—and all treated by the open method, with not a single death. He states that the results of open treatment are equally as good as with the antiseptic system, and he intends to employ it until proofs are brought that there is any better method.—*Br. Med. Jour.*, Dec. 30, 1876.

**TREATMENT OF SUFFOCATIVE GOITRE BY INJECTION OF IODINE OR THE USE OF SETONS.**—Mr. Lennox Browne, of London, advises strongly against excision of the thyroid, which he ranks as a highly dangerous operation, from the fatality which has been shown to be associated with it even in such skilled hands as those of Dr. Watson. He finds that a much simpler procedure will be successful, cause the disappearance of the tumor, and at worst only leave a slight scar; and he gives six cases of his own in support of his statements. The tincture of iodine may be injected, as recommended by Lücke, of Bern. In some cases it produces absorption, and in others suppuration; when the seton is used it is left *in situ*, so as to produce very long suppuration. In one case, where the tumor involved the isthmus and left lobe of the thyroid, and was as large as an orange, injections of the tincture of iodine were practised three times on alternate days, about thirty drops being used. Suppuration was then invited by fomentations, and, when the abscess formed, two further injections were made into the side swellings. The discharge took place spontaneously, and continued for four weeks, pledgets of lint being introduced into the wound, so that it might heal from the bottom. About nine months afterwards there was no sign either of tumor or scar. In another case, a young woman of twenty-two had a general fibrous enlargement of the thyroid. Swallowing had become difficult and breathing was embarrassed. An injection of iodine was made at the first visit. Great pain was occasioned, and the patient passed a sleepless

night. On the next day a seton was introduced and retained one month, and the effect was markedly beneficial, free discharges ensuing, and the tumor diminishing in size most markedly. A month later all discharge had ceased; there was no thickening perceptible, and the cicatrices were mere points. Her general health had also much improved. Mr. Browne has obtained very little advantage from electrolysis in these cases. Of eight patients who were thus treated, one only obtained real benefit. As auxiliary to the treatment, he recommends the patients to finish up by a course of baths and waters at the Bromo-Iodine Spa of Woodhall. Mr. Browne says it is difficult to say in which class of cases iodine is to be preferred and in which the seton. When the tumor is substernal and causes dyspnoea, it is the extension of the disease behind the trachea and oesophagus that is the cause of the trouble. These bronchoceles are usually small, and are always fibrous. The cystic bronchocele rarely embarrasses the respiration.—*Br. Med. Jour.*, Dec. 30, 1876.

**OPERATIVE TREATMENT OF CYSTS OF THE URACHUS.**—Dr. Roser, of Marburg, has had some experiences in these curious tumors, and has found in them so much that was interesting that he has thought them worth putting on record. In one case, the patient, a woman, could not pass her water at pleasure, for the compression of the bladder forced the water into the cyst, where it accumulated to the amount of three or four litres, its full capacity. Compression of the abdominal walls would then force the water through the urethra. Still, the amount passed in this way was small, and thorough evacuation could only be accomplished by catheterization. When first seen by Dr. Roser, she was in the third month of pregnancy; the uterus was slightly retroverted and depressed. The symptoms of extreme distention of the lower abdominal walls was relieved by puncture of the cyst, and in fact they did not recur during the remaining months of pregnancy, which terminated in a normal confinement.

Four years later, the same urgent symptoms called for the same operative procedure; but abortion followed, and afterwards the communication between cyst and bladder closed. Puncture of the abdominal walls was again done, and the patient regained her former condition of health, but the fistula remained open. It is now entirely closed, the only treatment being the withdrawal of the water, every two hours, by the catheter. In another case, Dr. Roser extirpated the cyst successfully, mistaking it at the time for an ovarian tumor. In Dr. Wolff's Inaugural Dissertation (Marburg, 1873) the following points are made, which, it is thought, may assist in a differential diagnosis. When a cyst is observed in the lower abdominal regions, growing slowly and gradually forwards, where it also has its attachment while (in woman) the uterus is depressed, it may be held to be a cyst of the urachus in an early stage. If the cyst be punctured, and flattened epithelium is found in the fluid, the likelihood will be increased. Cysts of the urachus are thought not to be as uncommon as is generally supposed. In fact, tumors, called ovarian, have in some instances been found to empty themselves through the bladder; and, besides, supposed ovarian tumors have more than once been removed, and the patient dying, the ovaries have been found unaffected.—*Archiv f. klin. Chir.* XX., 3, 1877.

**TREATMENT OF DIPHTHERIA.**—Mr. F. Knowles, of Ipswich, gives in the *Lancet* (Jan. 13) an account of the treatment of seventy-six cases of diphtheria occur-

ring in his practice during a severe epidemic in 1869. He says: "In each case I applied a strong solution of iodine to the false membrane—in mild cases once, in severe cases every six hours. After allowing the pigment to remain on for about the space of a minute, I directed the patient to hold a small quantity of the wash used by me in the throat for a few moments. On rejecting it, the false membrane invariably came away. In young children I used a soft camel-hair brush to remove the membrane. I never used force in any case to detach it, as practised by Loiseau. Although the exudation reformed, I found after each application the quantity was lessened and altered in character, being thinner and more fragile. The strength of the iodine I use, even for the youngest child, is: iodine, one drachm to two scruples; iodide of potassium, two scruples; rectified spirits of wine, one ounce. I use a brush made by Messrs. Maw & Co., which is fixed into a vulcanite stem. It possesses many advantages, being durable, very flexible, and moderate in price. The wash consists of a solution of chlorine and hydrochloric acid gas. It is prepared thus: Take of chlorate of potash, eight grains; put it in a pint bottle, with one drachm of pure hydrochloric acid, cork the bottle and shake it; as soon as the chlorate of potash is dissolved, add one ounce of distilled water, recork the bottle and shake it; repeat the process twice more, and then fill it up with water. I use equal parts of this solution and water; the addition of two drachms of tincture of myrrh to half a pint makes it much more agreeable.

"The internal treatment of this malady I consider most important. The one I always adopt is to administer the following mixture from the commencement of the attack: Chlorate of potash, one drachm; dilute nitro-muriatic acid, one drachm and a half; compound tincture of cinchona, three drachms; water to six ounces—one ounce to be taken every two or three hours, and dose in proportion to children. I believe chlorate of potash to have a special influence in preventing the formation of plastic material. When the submaxillary and neighboring glands are affected, I order linseed-meal poultices to be kept constantly applied. Inhalations of hot vinegar and water, in the proportion of one to three, I have often found very serviceable. In every case I ordered the patient to be well supplied with good, nourishing, digestible food, such as game soup, beef-tea, chicken broth, warm milk, eggs cooked and raw, and as much fresh-gathered fruit as wished for. Pontac and sound port were freely administered. In most of my cases the gangrenous odor emitted from the throat was almost intolerable. In very few of the cases was albumen present; but I noticed in several that the urine turned to a reddish violet on the addition of nitric acid and heat, which I suppose was due to the presence of purpura. The highest temperature I obtained, taken by thermometers tested at Kew, was 105°. Another fact worth mentioning is, that in only one case was any paralysis of the soft palate present; but in many cases there was hoarseness and weakness of the voice, which lasted some little time."

**SMALL-POX** still prevails to a considerable extent in England. In many of the larger towns it is epidemic. During the past year there has been a tendency to the occurrence of erysipelas after vaccination.

**A CROWDED PROFESSION.**—A physician of five years' experience wishes to obtain a situation with another practitioner who may desire to retire from active practice. We have no doubt that he will be overwhelmed with application.

# THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

## VISCERAL SYPHILIS.

DUE, undoubtedly, to the success of the debate upon the pathology of syphilis which took place last year before the Pathological Society of London, that body has decided that this year there shall be a debate at its meetings upon visceral syphilis. One of the results of the previous debate was to show that our knowledge of visceral syphilis in general was far from complete, and that it was probable that certain visceral lesions occurred in the secondary period of syphilis, of which we were almost ignorant, and further that many points particularly bearing upon the nature of these lesions, in hereditary syphilis, were as yet very obscure. It will be seen that the subject is a peculiarly appropriate one for such a body, and that if it is entered into in thorough spirit much good may result from its discussion. The first meeting occurred on the evening of the 16th of January, at which several interesting specimens were offered, bearing with them many important facts, but, unfortunately, there was very little comment. We shall present to our readers, from time to time, a general *résumé* of the subject, after the manner of last year, when the pathology of syphilis was under discussion.

The proceedings were opened by the address of Dr. Murchison, the newly-elected president, who made some very sensible remarks as to the function of the society, and as to its influence upon general medicine; he further made certain suggestions to its members as to the selection of specimens for presentation, which would be of benefit if heeded by members of similar societies in this country.

The subject of visceral syphilis being then in order Dr. Barlow exhibited an hereditarily syphilitic infant with enlargement of the spleen, traceable as low as the crest of the ileum, which also seemed to have heart disease, as a systolic murmur, audible at the apex and as far as the axilla, was made out. The child had been observed since its fourth month, when it presented the spleen swelling and the usual manifestations of

hereditary syphilis. Barlow stated that the form of swelling here exemplified was first described by Dr. Gee, who states that it can be felt in half of the cases, while one-fourth of the children having it die. As to the nature of the lesion little is known; it is not lardaceous and in one post-mortem examination no gummata were found, while in another there was capsular thickening. Barlow suggested that, according to the theory of Hutchinson, syphilis was simply a thinned-out fever; perhaps the condition was similar to that which obtains in typhoid.

Dr. Greenfield exhibited specimens taken from twenty-two cases of syphilitic disease in various stages, of affections of the dura mater, cerebral arteries, and of the brain and lungs, together with specimens illustrative of the growth and degeneration of gummata. Of the twenty-two cases, twelve were females, and ten were males, whose ages varied between twenty-three and forty years. While that of the females was between twenty-three and fifty years.

The majority of those who died directly from syphilis were comparatively young. Of the females under twenty-five, 1 died of accident, 1 from laryngeal disease, and 2 from thrombosis of the cerebral arteries. Of the males under forty, 1 died from diseases of the cerebral vessels, 1 from gummata in the brain and dura mater, 1 from laryngeal disease, and 2 from intercurrent troubles. In the females over thirty, the causes of death were: thrombosis of cerebral arteries, 2; of pulmonary artery, 1; of lardaceous kidneys, 2; peritonitis after colotomy for syphilitic stricture, 1; hæmoptysis in mild phthisis, 1; pyæmia, 1. Of the males over 40, one died of perforation of the dura mater by a gumma with resulting meningitis, 1 from laryngeal disease, 1 from lardaceous kidney, and another from cardiac dilatation. Thus fifteen out of twenty-one died directly from the effects of syphilis. It is to be remarked that amyloid degeneration was only found in four cases. In most of the cases, and all presenting cerebral lesions, there was no coexistent affection of the skin, though in some of them there were typical syphilitic cicatrices, and in the cases of laryngeal, rectal, and pulmonary disease the skin was also involved. In several of the cases, mostly female, there was atheroma, varying in extent, of the arteries. Greenfield then showed two specimens of syphilitic lesion of arteries. The first, an artery of the pia mater, near a cerebral gumma, appeared like a white fibrous cord. The walls of the vessels were much thickened and the channel greatly narrowed. The outer coat was infiltrated by a cellular growth, particularly noticeable around the vasa vasorum. While the middle coat was but slightly affected, the inner was greatly thickened, thus forming a large mass which nearly occluded the vessel. By high powers the growth in the inner coat was found to resemble that of fully developed gumma tissue, with capillaries of new formation running through it, the whole showing a tendency to organization. The

growth was separated from the blood channel by a distinct endothelial layer. The author regarded the changes as similar to those recently described by Heubner. The other specimen, from a case of very advanced and extensive disease of the cerebral arteries, was a section of a small artery of the cerebellum, in which the vessel was very nearly filled up by the thickening of its walls, which, consisting of hyperplastic change, seemed to involve all of the coats, it being doubtful whether the inner was the one mainly affected. The condition was similar to, but more advanced, than the first. Greenfield thinks that he has observed similar changes in the vessels of other organs, and that perhaps they played an important part in the degeneration of gummata. He then showed two specimens of disease of the lungs, which he thought to be due to syphilis. In one, from a female aged twenty-five, having typical ulcers on the legs; the change, limited to the middle of the lower left lobe, consisted of fibrous bands passing from the pleura inwards along the vessels, causing a contraction and puckering of its surface. By the microscope these bands were found to consist of fibroid thickening around the branches of the pulmonary artery. In the other case, from a man forty years of age, the disease, limited to the lower right lobe, consisted also of similar fibroid bands, producing a similar result to that of the first case, without any thickening of the pleura. This condition was found but twice in over six hundred autopsies, and in both cases evidences of syphilis existed. Dr. Gowers exhibited a specimen, called by him after Wagner, a syphiloma of the brain, which showed how that organ is invaded by syphilis by means of the meningeal vessels. He endorsed the generally accepted view, that intra cerebral gummata arise from the vessels of the processes of the pia mater between the convolutions. He further showed two coalesced nodules springing from the dura mater, composed of rounded nucleated cells,  $\frac{2000}{1000}$  to  $\frac{3000}{1000}$  of an inch in diameter, with fusiform cells and delicate fibrillary stroma, taken from a twelve-year-old child afflicted with hereditary syphilis. His third specimen was a nodule of the middle cerebral artery, showing syphilitic disease of arteries, from an adult male who had received the contagion fourteen years before. There was a large gumma in the anterior lobe, and the basilar artery was encircled by a new growth. The nodule was composed of small cell growth, with the usual fusiform cells and delicate fibrillary stroma, and appeared to arise in the outer coat. The inner coat was contracted and seemingly thickened, while the lumen of the vessel was filled with cells similar to those of the nodule, showing that the growth had been both outwards and inwards. Gowers showed a fourth specimen, a nodule from the lung of a patient who presented two gummata of the cerebellum. The nodule was about one-third of an inch in diameter, ill-defined in structure, with several caseous points. The structure was of round cell growth,

partly around vessels, and infiltrating the walls of the air cells, which were filled with new growth and inflammatory products. Though in structure it resembled the growth from the cerebrum, it was impossible to distinguish it histologically from tubercle.

Dr. Barlow exhibited specimens of syphilitic affections of the meninges and of choroiditis from a female infant seen by him, when one month old, having snuffles, but no rash, though its father was known to be syphilitic. He learned, three months later, that the child had had eleven fits, and he observed that it was wasted and that it presented symmetrical serpiginous ulcers of the nates. Later it suffered from laryngitis and contractions of the feet. In the fundus of each eye were specks of brownish exudation in the choroid, which suggested disease of the membranes. Shortly after the infant died, and on post-mortem examination the thoracic and abdominal viscera were found to be normal. In the skull there were several spots of adhesion between the arachnoid and dura mater, as well as some greenish lymph. The pia mater was thick and fibrous, and in one or two places its vessels were thickened and appeared like white threads. There were no granulations, and but few superficial spots of softening. Examination of the choroid membrane by Mr. Nettleship showed collections of corpuscles in the chorio-capillaris not arranged around the vessels.

These growths in the choroid differ from tubercle in not being like it of peri-vascular origin, and in not showing a tendency to caseation as the latter does. In the pia mater there was a great excess of fibrous tissue and a diffuse infiltration of nucleated lymphoid cells, while the vessels showed a growth in their inner and middle coats of such extent as to nearly occlude them. When they become thus occluded new vessels develop in their structures. The society then adjourned.

It will be seen that, in this, the first meeting, many facts of great interest were developed. The chief point shown by specimens was the arterial degeneration, recently well and thoroughly described by Heubner. We have here presented to us, in the specimens, the general outline of the course of this interesting lesion; and, although nothing new has been developed, the fact that independent observers arrive at similar conclusions to those advanced by Heubner, is important. The amount of knowledge thus far presented as to the nature of syphilitic pulmonary lesions is very small, but the features described by Greenfield, as occurring in the lungs of two syphilitic patients, are very interesting and suggestive. The results of the examination of Gowers and Barlow of the morbid products of hereditary syphilis are very important, though, as yet, fragmentary. Finally, the exhibition of the case of enlarged spleen in hereditary syphilis calls attention to a symptom which, though well known, has not of late years been much spoken of. We look forward with interest to the results of future meetings.

## Reviews and Notices of Books.

CHIRURGIE ANTISEPTIQUE: Principes, modes d'application et résultats du Pansement de Lister, par le Dr. JUST LUCAS-CHAMPIONNIÈRE. Paris: J. B. Baillière et Fils. 1876.

THE author, in a little brochure of 153 pages, gives an interesting and pleasantly written summary of anti-septic methods, as he saw them practised in Edinburgh by Mr. Lister, at first in the year 1868, and then in 1875. He believes that a six months' trial of the method at the Hôpital Temporaire last year, which, by the way, was the first systematic attempt to carry out Mr. Lister's plan in full—has sufficiently proven the great advantages of the plan. To those desiring to familiarize themselves with these matters, the theory on which they are based, the precise details of application, together with all the adjuncts, in the shape of antiseptic gauze, catgut ligatures, and drainage tubes, etc., the little book can be heartily recommended. It may be important for all surgeons to give this method a thorough trial, for it appears to have no theoretical objections to it—in fact, it inculcates certain principles that may prove to be of incalculable value to surgeons. One is the very careful cleansing of the hands of the operator and his assistants, as well as the instruments and appliances; then the use of catgut, which is apt to be unirritating and will melt away in a closed cavity; another is the withdrawal of matter by drainage tubes, while he is apt to leave the wounds as much as possible to themselves, the *pansement rare* of the French. We need not, in adopting the plan, believe with Mr. Lister that the results depend inevitably upon the truth of the vegetable germ theory, for the most recent observations appear to show that this evidence is very slender, nor do we have to believe that carbolic acid is the only agent, because it destroys vegetable growths, for several other substances used about wounds appear to be more potent in destroying and preventing the same kind of life. But carbolic acid doubtless has its advantages, which we may not yet wholly understand. One is, that it possesses the peculiar power of transudation directly through the tissues, and another is that it is an anæsthetic, as any one knows who has applied it to the raw surface in burns and scalds. We must not forget, however, that while the comparative results which Mr. Lister shows are exceedingly good, they are no better and sometimes not even so good as others here given. There is probably no test so good as the results of amputations, especially of the larger limbs, for there may be every degree of injury in compound fractures and the like, and it is on these that the friends of the Lister treatment lay great stress. How poor has been the success in these cases in some instances, we may judge from the fact that M. Labbé tells us, before the use of the antiseptic dressing in his hospital, compound fractures (fractures compliquées) were usually fatal. It is extremely difficult to get at the actual facts when statistics are given, but we may safely guarantee that few if any of the disciples of Lister have equalled the statistics of Burow, father and son, where 123 amputations were performed with only 9 deaths, of which there were 33 amputations of the thigh, with only 6 deaths, the dressing used in this case being the acetate of alumina; and they have certainly never surpassed the results of Alanson, of Liverpool, who, according to Dr. Stephen Smith, in the year 1779 reported 33 consecutive amputations of the thigh in unselected cases, with no deaths at all.

## THE TREATMENT OF CHLOROFORM POISONING.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—The deaths from chloroform in the new year are already forming subjects for consideration, as is evident from the articles referring to them in recent numbers of your valuable journal.

In neither of the cases, mentioned in the RECORD, were the apparent antidotal properties of the nitrite of amyl tested. Both in a recent paper,\* and in articles upon the subject, I have shown that physiological experiments upon animals, and trials with it upon the human subject in apparently impending collapse from chloroform, have developed an antagonism between the effects of chloroform and nitrite of amyl. My object, at present, is to call attention to these properties, with the hope that "the nitrite of amyl may be at hand as one of the remedies, whose efficiency is to be tested in case of impending danger," from chloroform. It may be easily carried in the glass capsules which are made for that purpose, may be administered hypodermically, or held to the mouth during artificial respiration, and its use is not considered dangerous, at all events, in ordinary doses, by those who have tried it fully. There are so many who still consider chloroform as a safe anæsthetic that it will not yet be abandoned, and therefore any method or medicine, which is likely to avert those dangers which attend so unexpectedly the use of chloroform, is worthy of a trial.

Respectfully,

F. A. BURRALL, M.D.

## PNEUMONIA ARRESTED IN FIRST STAGE.

TO THE EDITOR OF THE MEDICAL RECORD.

INSTANCES of resolution of pneumonitis in the first stage, though mentioned by a few writers, are rare enough to warrant the publication of the following case:

H. C., *ætat* 42, a strongly built man, of regular habits, sent for me January 1st, 1877. Late on the preceding evening he had been seized with a violent chill, followed by fever, pain in right chest, dyspnoea, and headache. On my visit, at 2 P.M., his temperature was 101.6; pulse, 128; respiration, 26; pain, increased by coughing or breathing, in axillary region at level of right nipple. Inspiratory crepitus and scarcely perceptible dullness over a place about the size of a hand-palm. Cough frequent; sputa tenacious and colorless. I ordered turpentine stupes, to be repeated twice in the twenty-four hours, followed by cotton-battling and oiled-silk jacket, and prescribed tinct. aconit. rad., ℥j.; liq. morph. sulphat. magend., ℥j.; vin. ipecac, ℥v., in mixture every two hours.

Jan. 2d, 2 P.M., temp. 100.1; pulse 104; respiration 20. Slightly delirious during night; pain easier, but still distressing on coughing; dullness not increased; subcrepitant râles; sputa more abundant; mucus, not at all "rusty."

Jan. 3d, 1:30 P.M., temp., 101; pulse, 104; respiration, 17; cough, very "loose," but not frequent; sputa mucus, profuse and colorless; pain quite re-

lieved; large moist râles on right side; percussion sound normal.

Jan. 4th, 2:30 P.M., temp. 103; pulse, 108; respiration, 24; cough almost gone; "sputa cocta"; pain felt only on deep inspiration. Bowels not having been moved for forty-eight hours, ordered magnes. citrat. and, in addition to the aconite mixture, quinine-sulf. sat. grs. iv *per die*.

Jan. 5th, 2 P.M., temp., 100.3; pulse, 96; respiration, 17.

Jan. 6th, 2 P.M., temp. 98; pulse, 84; respiration, 16; and thenceforth recovery was uninterrupted.

Concerning the diagnosis at the outset, I think there can be little doubt. The interesting feature of the case is the apparent relief of the engorged tissues by copious mucous secretion without capillary rupture or hepatization. At no time was there any semblance of "rusty" expectoration, nor any physical signs of the second stage of pneumonia. The marked rise of temperature on the 4th seems to have been due rather to intestinal irritation than to any pneumonic process, and can scarcely be ranked with the elevation which sometimes precedes defervescence in severe cases. The cotton and oiled-silk jacket was worn steadily, and the turpentine stipes applied morning and evening while the pain lasted. Whether treatment served to limit the morbid action, or whether there are occasional cases in which pneumonia is spontaneously aborted in the first stage, is a question which future observation may decide.

ALFRED L. CARROLL, M.D.

NEW BRIGHTON, N. Y.

## REPORT OF TWO CASES OF PLEURITIC EFFUSION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—I send you a report of two cases of pleuritic effusion, which may prove interesting to the readers of your JOURNAL, in connection with Dr. Robinson's article recently published by you.

In September, 1876, I was consulted by Col. S., aged about 70, an unusually stout and well-preserved man for his age with regard to a pain in his right side. Physical examination failed to reveal a pleurisy. The pulse was not accelerated, neither was there dyspnea on exertion. As Col. S. was going about as usual, I made no thermometrical examination. I was able to exclude neuralgia and all hepatic trouble. As the pain was most severe about the eighth and ninth ribs laterally, I concluded it must be myalgic. This opinion was farther strengthened, when, in reply to my question, he replied, that a few days before, to keep himself from falling, he had made a violent muscular exertion, and immediately felt a pain in his right side, which he described as a cramp. I placed him on tonic treatment, and applied an aconite liniment over the painful part. He remained in Frankfort two weeks after this; seemed to improve, and continued to attend to his business as usual. About October 1st he went to his plantation in Arkansas. I learned that he grew constantly worse after leaving Kentucky. Some time during this month he consulted a physician near him, who told him he had neuralgia. I do not know that any physical examination was made, at least his condition was not made known to him. Col. S. continued to take moderate exercise by riding over his plantation and occasionally fishing, though he complained more after exercising than he did when in Kentucky. He was never confined to his bed. Continuing to grow worse, however,

he concluded to go to New Orleans and consult Dr. Choppin. Arriving there November 2, Dr. C. was at once called to see him on board the steamer. He pronounced Col. S.'s condition a very critical one, because of extensive pleuritic effusion. A few hours afterward, his son left him for a few moments, and on returning, found his father dead. The death was from apnea or possibly from the twisting of some large blood-vessel upon itself. No post-mortem examination was made.

This case is an illustration of the too common occurrence of sudden death from effusion into the pleural sac.

I cannot say that I made a culpable error in diagnosing this case during the time he was under my care. With the exception of pain, the rational symptoms of pleurisy were absent. There might possibly have been slight pleuritic effusion, when I made the physical examination. Fraentzel, for himself, and quoting Wintich, denies the possibility of diagnosing slight pleuritic effusion. I am certain there was no pleuritic friction sound, and I believe in most cases of *subacute* pleurisy this physical sign is absent. After the effusion became more extensive, the nature of the trouble was the more evident. I have but little doubt that Dr. Choppin would in a day or two have relieved Col. S. (at least temporarily), by the use of the aspirator. The case is, at least, instructive in its clinical history and final result.

Mr. N., aged 45, was taken sick Jan. 15, 1877. As I was absent from home, from this time until the 24th, he was attended by Dr. Wilhoite. Dr. W. diagnosed pleuro-pneumonia, and treated him accordingly, paying more attention to the pneumonia than the pleurisy. On the 23d, Mr. N. expressed himself as being much better, and dismissed Dr. W., who supposed his patient convalescing. January 30th I was sent for. Pulse, 96; respiration, 24; temperature, 101. Left side half an inch *smaller* than right; respiratory movement *quite marked*; fremitus on left side almost disappeared; flatness over same side complete, except immediately under clavicle, where Skodaic or tympanitic resonance was quite marked, and also slight tympanitic resonance in supra-spinous fossa; absence of vesicular breathing over left lung; bronchial breathing distinctly heard, and bronchophony very decided over the posterior part of the lung. I could discover no *agophony* nor gurgling. There was no displacement of the heart towards the right side, and no bulging of intercostal spaces. Left hypochondriac region slightly larger than right, but no perceptible displacement of the spleen. Succussion negative, and change of position made no alteration in area of dullness. Right lung normal.

*Diagnosis.*—Pleuritic effusion of left side, with possible inflammatory solidification of lung tissue. Ordered teaspoonful of Basham's mixture, t.i.d., and mercurial ointment to be rubbed into the side. (A year since I treated Mr. N. for pleurisy, with slight effusion of right side, with Basham's mixture and croton-oil paint. The success was perfect.) 31st, no perceptible change. February 1st, I was unable to see him. 2d, his son reports that his father complains of shortness of breath. February 3d (this morning), I concluded to aspirate the chest. On examination his condition was the same as on January 30th, date of my first visit, except that the breathing was more labored. I wish it distinctly remembered, that the left side was smaller than the right, by half an inch; respiratory movement well marked over this side; no bulging of intercostal spaces, and no displacement of the heart; its impulse, however, was unusually indis-

finet and feeble, out of proportion to the volume and strength of the pulse. I introduced the needle of the aspirator in the eighth intercostal space, at the anterior border of the latissimus dorsi, and to my utter astonishment removed, by actual measurement, *three quarts and three ounces* of serum. The serum came into the cylinder of the aspirator, the last filling as readily as during the first, and showed no signs of increasing turbidity, but my hands were cramped from manipulating the piston and holding the instrument steady (which, by the by, is very tedious in a long sitting), and during a sudden movement of Mr. N. I incautiously let go, and the needle dropp'd out of the chest. I did not reintroduce it, being pretty well satisfied with the result already obtained. On examination, the line of dulness is lowered to the level of the fifth rib, but considerable thickening of the pleural sac is evident. I, of course, do not know how much fluid remained in the pleural cavity, probably two or three pints. I expected to find fluid, but was astonished at the enormous quantity which was in the chest—not because the chest cannot hold this much (a gallon being frequently removed or found at post-mortem examination), but because the usual evidences of excessive effusion, as bulging of intercostal spaces, increased size of affected side, and displacement of the heart, were absent. Fraentzel mentions the fact, that sometimes in pleurisy of left side the heart becomes attached to the lung by adhesions, and, therefore, cannot be displaced to the right, but I would think that if the lung be pushed so far up towards the apex (as it usually is), that it would certainly raise the apex beat of the heart very perceptibly. I offer no explanation of the other rare appearances, but merely state the fact.

The history of this case is of course incomplete, as I have it yet under my care, and may probably aspirate again. But the final result is (*to your readers*) of secondary importance to the fact of the peculiar conditions existing with such an amount of liquid. I send the report now, as it may serve as an illustration of some point discussed in the article on effusions into the pleural sac, published in the Record, and to which allusion has already been made.

For myself, I am a strong believer in early paracentesis thoracis (especially since the use of the aspirator), having this opinion inculcated by my father before me, who frequently and successfully resorted to this procedure.

W. B. RODMAN, M.D.

FRANKFORT, KY., 1877.

## CROUP AND DIPHTHERIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Together with many others of the medical public I have listened with great interest to the discussion at the Academy, still to be continued, on the relations between diphtheria and croup. I have been struck by the fact that, among all the opinions hitherto expressed, has not yet been presented the one held by so many European investigators: namely, that the croup which occurs in the course of diphtheria, is not a diphtheritic process, but an ordinary inflammatory process, *consequent* upon the local and constitutional conditions of the disease.\*

When croup has been produced artificially in the

larynx, by means of diphtheritic membranes introduced into the air-passages, the *appearance* of the croupal membrane has been identical with that of membranes formed after the introduction of chemical irritants, as ammonia.\* Only in the latter case the false membranes were not contagious; in the former they proved to be so, by infecting the animals upon whom they were transported. All writers who rest the peculiarity of the diphtheritic exudations upon the presence in it of a special kind of bacteria (*Micrococcus diphtheriticus*, Klebs; *Zygodonimus fuscus*, Letzerich), admit that this parasite is never found in the larynx below the vocal cords. Senator, who denies the existence of special diphtheric bacteria, is nevertheless among those who admit a radical difference between the "fibrinous exudation in larynx and trachea," seated upon an intensely hyperamiated mucous membrane, and the "exudation in the pharynx, composed of a network of degenerated epithelium, fine granules, and micrococci, which, as the disease progresses and *inflammation is set up*, becomes a true eschar, covering an ulcerated mucous membrane, and containing detritus of its surface, together with pus-cells and blood-corpuscles." "The characteristic lesion of diphtheria is an acute necrosis." "On the contrary, the croup membrane of larynx and trachea, is an exudation in the narrowest sense, consisting of fibrine and blood corpuscles."† or, as Wagner describes it: "The so-called croup membrane consists of a thick network of delicate fibres, and of extremely numerous elements, similar to pus-corpuscles, lying in its meshes. . . . It develops by degeneration of the cylinder epithelium of the lower larynx and trachea, in the same way as the diphtheritic membrane from degeneration of the pavement epithelium of the pharynx. . . . Between the croup exudation and the surface of the mucous membrane, is a thin layer of muco-purulent fluid, and underneath, the tissues are hyperamiated, and the seat of a moderate infiltration of pus corpuscles and free nuclei, almost confined to the superficial layers. . . . But underneath the diphtheritic exudation, the infiltration is intense, and extends to the submucosa."‡

According to Buhl, this infiltration is the most characteristic circumstance in the local processes of diphtheria, and which most distinctly defines it as a "general infectious disease." The author compares the infiltration with that observed in the primitive lesions of syphilis and of tuberculosis. Croup, on the other hand, is a local inflammation—an intensification of a catarrh, *secondary* to diphtheria in most cases, even when occurring in the course of that disease. The mucous membrane is superficially infiltrated, but with pus-corpuscles, and not with elements, which, Buhl maintains, are in diphtheria derived from conjunctive tissue cells, and tend to organize.§ This doctrine corresponds to, although it be not quite identical with, the well-known distinction established by Virchow between "diphtheritic" and "croupal" inflammation.¶ It is much ridiculed by Sarré, author of a recent excellent systematic treatise on diphtheria.\* "By a deplorable abuse of language," observes the French writer, "applying to pathological processes the terms which served to designate diseases, writes on the other side of the Rhine have, after the

\* See Birsch Hirschfeld: Archiv der Heilkunde, 1873; Eberth: Ueber Diphtheritis; Letzerich: Archiv Virch., Bd. 53; Klebs: Ueber Diphtheritis; Senator: Ueber Synanche contagiosa, Volkmann Saunm-lung, No. 78, 1874; Wagner: Arch. der Heilkunde, 1866, Bd. 7; Buhl Zeitschrift für Biol., III., 1868; Rindfleisch: Path. Anat.; Waldenburg: Berlin, Klin. Wochenschr., 1872.

example of Virchow, called *croupal inflammation*, a phlegmasia, which, without involving the structure of the mucous membrane, deposits on its surface an exudation—a false membrane; and *diphtheritic inflammation*, an interstitial phlegmasia characterized by a sero-fibrinous exudation, which infiltrates tissues and causes their mortification. . . . Thus they have created the whimsical denominations, *croupal pneumonia*, *croupal nephritis*, on the pretext that in these cases the fibrinous exudation is effected into the pulmonary vesicles or the renal tubuli.\*

Sanné considers equally *bizarre* the views of Wagner, who, "arranging pathology to suit his anatomical conceptions, maintains that a patient may have at the same time, by simple coincidence, two different diseases; diphtheria in the pharynx and supra-glottidean part of the larynx, and croup in the infra-glottidean part, and in the trachea."† "The only true view is to consider diphtheria as always the same process, susceptible of assuming distinct anatomical forms according to the organ on which it is localized."

Here the author makes the very confusion between the disease and the anatomical conditions which he has so emphatically condemned. The distinction is of importance precisely in relation to the question now under discussion at the Academy, namely, the identity or non-identity of sporadic croup, and of croup occurring in the course of diphtheria. The assertion of identity can mean nothing, except as regards etiology and contagion. The laryngeal lesions are identical as proved by the examination of both clinical and experimental cases. I have recently had an opportunity to examine the larynx and trachea in a considerable number of cases of diphtheric croup, and to compare them with a few of intense catarrhal laryngitis. In the former cases existed all the lesions of the latter, namely, fall of the epithelium, infiltration of the mucous membrane, by greater or less number of small round cells, great dilatation of blood-vessels, and frequent ecchymoses. The additional lesion in the croup was, of course, the false membrane, lying now upon parts where the epithelium was still intact, now where the mucous membrane had become denuded. The differences of opinion which concern the false membrane in the pharynx do not exist for the larynx; every one admits that it is a fibrinous exudation, whose organization into adhesions, similar to those of pleuritis and peritonitis, is only prevented by the rapid termination of the disease. "Fibrinous inflammations in general represent a more elevated degree of irritation than serous phlegmasia." "The blood is doubtless the principal source of the exudation, but it is not probable that this product of inflammation pre-exists in the blood. . . . We must admit that the inflamed tissues have the property of so modifying the serosity coming from the vessels, that this is changed into concrescible plasma or fibrin. This fibrinogen property would be due, according to Chalyet, to the process of denutrition which succeeds to the stage of cellular irritation, that is to say, to the materials accumulated during the *deshicence* of inflamed conjunctive tissues."‡

Let it be admitted that tissues, dying from excessive hyperemia when the blood in the diluted vessels has been altered by diphtheritic poison, would afford material possessed of more intensely irritative properties than those affected by the hyperemia of ordinary catarrh. We should then approximatively understand

the frequency of croup in diphtheria, as compared to its occurrence in non-specific pharyngitis, where the local conditions of irritation may be very much the same. But there is nothing to exclude the possibility of other causes concurring to produce the same result, namely, the communication of a fibrinogen property to the hyperemiated epithelium or conjunctive tissues of the laryngeal mucous membrane. The question is, therefore, not Is croup diphtheria? but, admitting that diphtheria may be a cause of croup, Canot croup be caused by something else as well?—as Oertel produced false membranes in the larynx and trachea of rabbits, by introducing on the one hand false membranes from diphtheritic patients—on the other, non-specific chemical irritants.

The distinguishing test has frequently been sought for—clinically, as in Oertel's experiments—in the capacity of these false membranes to infect other animals. I do not think that this experiment has ever been made with the false membranes derived from a case of "idiopathic" croup, although the contagiousness of this latter disease has of course been alleged as indisputable proof of its diphtheritic etiology. In the same way, the development of scarlatina in a family, immediately after a case of nephritis, awakens suspicion of the scarlatinous origin for the latter, in which a characteristic angina had been overlooked. But no one on that account would presume that nephritis could never be anything else than a symptom of scarlatina. The relations between diphtheria and croup may be aptly compared to those between scarlatina and nephritis. In each case exists a specific constitutional disease with lesions characteristic or even peculiar to itself, and in each case, also, these specific lesions may be accompanied by a varying outége of non-specific lesions, which latter may be encountered in various other groups of morbid phenomena. In each case, finally, the anatomical products of these non-specific lesions may serve to transmit the specific disease, simply because all the particles thrown off from a living body at any given time tend to reproduce themselves in their entirety, consequently with the poison with which they have become impregnated while part of that body, as soon as they can find an appropriate soil for development. Living particles from healthy bodies only tend to grow, to excite excessive local growth; hence production of pus, when they can gain admittance below the epithelium of other living bodies.\* Similar particles thrown off from diseased organisms, though from parts not exhibiting the specific lesions of the disease, must similarly tend—proportionately to the degree of constitutional infection—to reproduce themselves, and with themselves the poison. Hence the inoculability of croupous membranes from an individual affected with diphtheria would still not prove that these were in any sense diphtheritic—still less, therefore, that all false membranes in the larynx or trachea must be proof of diphtheritic poisons.

The above remarks apply especially to the croup of children, in whom, from the smallness of the throat, the larynx lies much nearer to the seat of irritation set up by pharyngeal diphtheria, and inflammations from contiguity and inflammatory oedema are therefore facilitated. In the much rarer cases of croup complications, in the diphtheria of adults, it is admitted that a true *extension* of the original diphtheritic process will much oftener be found. In the single case we have had an opportunity of examining (only macroscopically), the epiglottitis and entire larynx were

† P. 40.

‡ Lancereaux, *Anatomic Pathologique*, p. 237, 1875. According to Buhl, the proliferating epithelium form within themselves a substance similar to fibrine, and throw it off together with the pus-corpuscles.

\* Essentially the theory of Beale, which seems to us much more comprehensive than that of specific bacteria.

ulcerated and covered with pultaceous exudations, entirely resembling those of the pharynx. Wagner, especially, gives a special description of laryngeal diphtheria in *adults*. Besides the theoretical interest of this question, is a practical inference from the theory of croup as an inflammation induced by intense irritation of adjacent parts: we should be cautioned against irritating therapeutics, which may serve to precipitate the very lesion they propose to heroically avert.

**HYDROBROMIC ACID AND QUININE.**

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—In No. 320 of the MEDICAL RECORD there was published a communication in regard to the use of hydrobromic acid in combination with quinine, as a means of preventing the tinnitus aurium caused by the latter remedy. The statement is made by the correspondent, that the acid may be given in doses of a half drachm, combined with quinine, and enclosed in capsules.

Hydrobromic acid, like its analogous compound, hydrochloric acid, is a gas in its pure state at an ordinary temperature. It liquefies at a temperature of 100° below zero, and becomes solid at 124°. The gas is very soluble in water, a concentrated solution having a sp. gr. of 1.486. (See Brande and Taylor's "Chemistry.") This solution is a very caustic liquid, and cannot, except when largely diluted, be administered internally. In no manner can half a dram of this liquid be combined with quinine and given in a capsule.

The following prescription was given in that communication:

R Quin. sulph. . . . . ʒi.  
Hydrobromic acid,  
Aqua . . . . . ʒiiss.

With the statement that two teaspoonfuls contained five grains of quinine.

If any physician should write this prescription without giving specific directions as to the strength or manufacture of the hydrobromic acid, very serious results would be likely to follow. The druggist in preparing the prescription would probably use the acid made by Merck, or that of some other manufacturer equally strong. The effect of an acid as corrosive as the concentrated hydrochloric acid, diluted with only an equal portion of water, would indeed be serious, if not fatal. It was only by the intelligence of one of our Brooklyn druggists that a disaster from this cause, and probably having its origin in the communication referred to, was prevented.

It is true that Fothergill's formula for preparing the acid was subjoined to the prescription of your correspondent. How few physicians can stop to inquire of druggists if they have the acid prepared according to this formula! How few will subjoin the formula to their own prescriptions! And how few will think or know of the difference in strength between this acid and that prepared by Merck.

I know nothing of the therapeutic effect of this acid, but if it will indeed prevent the tinnitus aurium of cinchonism, we shall be glad to see an official "Dilute Hydrobromic Acid" entered in its proper place among the medicines of our pharmacopœia.

M. D.

THE ASSOCIATION OF THE ALUMNI OF THE COLLEGE OF PHYSICIANS AND SURGEONS, IN THE CITY OF NEW YORK, 1877.—The annual meeting of the Association will be held at the College building, corner of Twenty-third street and Fourth avenue, on Wednesday, Feb. 28, 1877, at 8 o'clock P.M.

The annual dinner of the Alumni Association will be held, March 2, 1877, at Delmonico's. Tickets may be procured of any member of the committee, George M. Lefferts, John C. Barron, F. P. Kinnicut, T. M. Cheesman, or F. P. Foster.

VARIABLENESS IN TINCTURES AND FLUID EXTRACTS.—Mr. C. K. Smith obtained from six manufacturers samples of fluid extracts sold by them. These he evaporated to a pilular consistence, and weighed the residue. The same quantity being in each case taken, the results were as follows:

	1	2	3	4	5	6
	grs.	grs.	grs.	grs.	grs.	grs.
Ext. gent. fluid.	360	800	1070	720	1140	850
" senneæ "	840	1010	720	540	1280	825
" rhei "	480	125	1210	960	1500	800
" scillæ "	1000	1068	150	800	1600	1080
" ergotæ "	480	420	750	480	780	780

Mr. Wm. D. Robinson examined seventeen samples of *Tinc. Cinch. Co.*, in which he found the total quantities of alkaloids present represented by the following percentages: .287, .81, .871, 1.03, 1.09, 1.13, 1.20, 1.27, 1.38, 1.62, 1.71, 2.05, 2.13, 3.09, 3.11, and 4.46. —(*Am. Jour. of Pharmacy, Jan., 1877.*)

PATHOLOGY AT THE ROADSIDE.—An extraordinary scene was witnessed a short time since on the public road near the village of Carrington, a few miles from Edinburgh. An old woman had died suddenly at

CHARITY HOSPITAL.—Dr. John J. Reid has been appointed visiting physician to Charity Hospital, vice Dr. W. DeForrest Woodruff, deceased.

that village at the beginning of the week, and post-mortem examination had been ordered by the parish authorities. According to instruction, a medical man, accompanied by his assistant and a sheriff's officer, went to the house of the deceased for the purpose of making the examination. To their surprise, they were told, on arrival, that the corpse was on its way to be buried: upon which they hurried after the funeral party, and caught them up before the graveyard was reached. Their proposition that the body should be taken back to the house for the intended examination was resisted by the people in charge of the funeral; and the sheriff's officer had to stop the coffin, which was being carried country fashion, and placed it upon a roadside heap. The doctor had the coffin opened, and there and then made his examination of the corpse. This over, the coffin-lid was retastened and the funeral duly proceeded with.—*British Medical Journal*.

**EXTREME PLUMBISM TREATED BY GALVANIC BATHS.**—Mr. S. J. Knott, Medical Superintendent of Galvanism to St. Mary's Hospital, reports (*London Lancet*, No. 16, vol. ii., 1876) a case of extreme and well-marked plumbism, that for five months and a half defied all drugs as well as local faradizations and galvanizations, and yielded promptly to galvanic baths. The patient was admitted to the hospital, June 22, 1875. Had lost control of both flexors and extensors of upper as well as lower extremities; also exhibited aphonia, great emaciation, constipation, etc.; blue-line of margin of gums well marked; history of plumbism, including several attacks of colic. The urine yielded gr.  $\frac{1}{100}$  of lead per fluid ounce. On December 4th, all other treatment having in the meantime proved unavailing, the daily administration of galvanic baths was begun. From this date he commenced to improve. All medicine was soon discontinued, the baths constituting the sole treatment. A few weeks sufficed to effect a complete cure. Dr. Handfield Jones tested the water of the bath both before and after this; the results before the bath were negative; after the bath well-marked traces of lead were found. Under the influence of the baths, the patient seemed to undergo a perfect regeneration of muscular fibre. Mr. K. also states that cases of ordinary lead colic and dropped wrists treated by this method have recovered in a few days, without medicine.

**NEW THERMO CAUTERY.**—Dr. Paquelin (*Lancet*, January 29) has devised a new apparatus for thermo-cautery, which is simple, handy, and efficient. It consists of a hollow handle, insulated with wood to protect the hands from the heat, and is furnished with movable platinum heads, corresponding in form to the cautery irons found generally useful. Into these cauteries, which are hollow, after they have been heated to blackness in the flame of a spirit lamp, a blast of benzoline vapor is introduced by means of an ordinary spray bellows, which at once raises to and maintains them at a state of vivid incandescence. The heat thus produced can be kept up for an indefinite time by slightly compressing the bellows occasionally.

**TREATMENT OF TYPHOID FEVER.**—Recently a long and spirited discussion, upon the treatment of typhoid fever, took place at the Société Médicale des Hôpitaux. The question turned upon the value of the cold bath as a therapeutic agent. The experiences of the Parisian physicians, during the recent epidemic of typhoid, so far from establishing the value of cold baths as compared with other remedial agents, really prove that the mortality is somewhat increased by them.

**A PIECE OF GLASS SWALLOWED.**—Mr. Eison (*Lancet*) reports the case of a man who swallowed a triangular piece of glass, three-quarters of an inch in length, while drinking some beer. The foreign body safely traversed the intestinal canal, and being caught in the lower portion of the rectum, was easily removed by operation. The case is worthy of note, considering the nature of the obstruction and the escape of any injury to the intestines during its perilous passage.

**THE CONVICT INSANE.**—Dr. Carlos F. MacDonald, the recently appointed medical superintendent of the State Asylum for Insane Criminals at Auburn, N. Y., in his report for 1876, says: "I may, however, briefly allude to one fact, in relation to insane convicts, which I do not remember to have observed during an experience of several years in a hospital for the ordinary insane, and which has fully convinced me of the wisdom of providing a separate institution for the treatment of this class of patients. The fact to which I refer is the frequency of cases, among the convict insane, in which "sin and madness" are so closely allied as to almost defy separation; and I am obliged to confess, that during my short experience here, I have met with a few cases in which it was very difficult to decide whether the principle underlying their outward manifestations was depravity or disease. According to my observation, the chief characteristics of these cases are absence of moral sense, absence of delusions, while the intellectual faculties, such as they are, apparently remain intact. They seem to have the arts of lying and theft developed to the highest degree, the former of which they diligently make use of to create mischief and disturbance. They have bad tempers, which they not infrequently exhibit, their paroxysms of passion being followed by a sullen, moody state."

**SALARIES OF PROFESSORS IN THE GERMAN MEDICAL SCHOOLS.**—In Prussia and several of the duchies the salaries of the medical professors are not fixed by law, but practically they do not descend below a fixed minimum figure. They vary between \$450 and \$1,900, to which must be added the indemnity for lodgings paid to those members of the corps of teachers who do not reside in the universities. In Switzerland the salaries of the regular professors vary from \$500 to \$1,000, but certain chairs are specially endowed, and the government often pays more to teachers whom it is desirable to retain in the country. In Russia the regular professors receive about \$2,000, and the assistants about \$1,350, but the figure varies according to the importance of the university and the value attached to the services of an individual teacher by the government. In Tübingen the salaries are fixed at \$1,800, \$2,000, and \$2,200 for the three grades of professorships. In the three universities of Bavaria the professors receive about \$800, and the assistants about \$600, with a small increase after every five years of service. In Austria the salaries have often been changed. The law of April 9, 1870, fixed the salary of professors in Vienna at \$1,100, in Prague at \$1,000, and in Innsbruck, Gratz, &c., at \$900. There, too, there is an increase of salary after every five years of service, and also a sum allowed for house hire.

These salaries are not large, but the professors may also make private contracts with the government, and in that way the more illustrious among them receive more adequate compensation. Some of them receive salaries of \$3,000, \$4,000, and \$5,000. Prof. Recklinghausen receives \$6,000, and with the fees of the students his chair is worth more than \$8,000.—*Lyon Médical*, Oct. 15.

## Original Lectures.

### ON THE PLANS FOR THE JOHNS HOPKINS HOSPITAL AT BALTIMORE.

A LECTURE GIVEN TO THE MEDICAL PROFESSION OF BALTIMORE, FEBRUARY 5, 1877.

By J. S. BILLINGS, M.D.,  
SURGEON UNITED STATES ARMY.

#### PART I.

GENTLEMEN:—Before a final decision was made on the plans for the Johns Hopkins Hospital, prepared and submitted to the trustees last year, it was thought desirable that they should be compared with the most recent plans for similar institutions in Europe, and that opinions and criticisms upon them should be obtained from those who have given most attention to such subjects abroad as well as at home.

For this purpose, and also for others connected with my duties at Washington, having obtained a leave of absence, I landed at Queenstown, October 16th, and re-embarked from Liverpool, December 16th, having during the sixty days of interval visited the principal cities in Great Britain and Western Europe, and having at each place examined the hospitals and medical schools, and conferred with those most interested in such matters, so far as the very limited time at my disposal would permit. On my return I presented briefly the results of my observations and inquiries to the trustees, and it has been thought that a part of this statement might be of interest to the medical profession in this city, hence I propose to-night to speak of the hospital and its plans more especially from a professional point of view. I do not propose to go into details as to what I saw and heard in Europe, but merely to state general conclusions. I may say, however, that I was everywhere received with the greatest kindness and hospitality, and every facility was given me to see what I wished to see,—that I found the Johns Hopkins trusts well known by name everywhere, and that much interest and curiosity is felt by medical men there as well as here as to the course which is to be taken by this medical school and hospital.

One of the objects of my visit had reference to the extension and improvement of the National Medical Library at Washington, and a comparison of its resources and mode of management with those of some of the celebrated collections of Europe. I find that in point of size this is one of the largest separate medical libraries in the world, the largest ones in Europe being those of the Royal College of Surgeons, and of the Royal Medico-Chirurgical Society of London, of the Royal College of Physicians in Edinburgh, and of the Medical Department of the Prussian Army at the Friedrich Wilhelm Institut at Berlin, which last is under the charge of an army surgeon, Dr. Sachse, and is one of the most valuable and best arranged on the continent.

With reference to the subject of medical education, and the views which I have elsewhere expressed as to the relations which should exist between the hospital and the medical department of the university, I find that I am in accord with all or nearly all of those whose opinions on this matter I was able to obtain. These views may be stated as follows:

The ideal medical student for this university should be a graduate in arts, and should have taken a special course during the last one or two years of his academic career. He should then spend two years in the study

of the theoretical branches and in work in the dissecting room and laboratories. The next year, while continuing these studies, he should begin clinical work in the dispensary, and be shown certain cases in the hospital. The fourth and last year he should devote entirely to the study of disease, and for this purpose he should reside in the hospital. Having completed this course and graduated, the post of resident physician for another year is open to his competition, or he can take a special course suited to make him an expert in state or preventive medicine. A student from another school should be allowed to take that place in the course which proper tests show him to be fitted for, and the idle or incompetent should be unsparingly thrown out by a series of successive examinations. As the graduating class is to reside and be employed in the hospital, its number must be limited by the plan of construction, and the number I have selected is twenty-five.

Thus far I have considered the question as if the object of this hospital, so far as it is to be a part of the medical school, were to allow the students to become acquainted with the forms and accepted modes of treatment of various diseases in order that they may recognize and similarly treat them when met in their practice, thus doing merely what other hospitals connected in like manner do, only perhaps a little better and more thoroughly than is usual. But is it not also possible that in this hospital every instrument of precision and means of investigation known to the physician, the chemist, and the physiologist, may be applied to increase our knowledge of disease and of the action of remedies, by or under the supervision of men specially trained to observe, accurately record, and scientifically deduce from such records new points for inquiry, and new means of making such inquiries, and so on in a sort of arithmetical progression? Here and there in the world there are a few men engaged in such researches, but they are few and widely scattered; those who have the means usually have not the time, and those who have the time have not the means. It requires, moreover, something more than time and means to make valuable observations in so difficult a science as medicine: to get the best results, the observer must have, besides natural ability, a special training. In short, I would have in this hospital the professors and lecturers and students all to be seekers and learners together, each in his own place, and if twenty-five, or ten, or even only three such graduates as I would have them, can be produced each year, it will repay the effort. They will be fitted to be general practitioners no doubt, but they will also be fitted to undertake special work which the average graduate would not dream of attempting.

I do not find that those physicians whom I have consulted at home and abroad think that this is aiming too high; at all events, no harm can come of trying. If there are any young men in this country able and willing to do such work as I have indicated, let us give them the opportunity to do it; if there are none, we shall not be worse off than other hospitals, at all events. I am not aware that there is at present any urgent demand either by the medical profession or the public for more doctors certainly not for more than the institutions at present engaged in manufacturing them are able to supply; but there does seem to be a demand among the leading thinkers among our physicians, for some men fitted to be investigators and discoverers.

Two objections have been made to this plan. The first is offered by some American physicians, who fear that the requirements are so great and the course of

study so long, that there will be very few students — too few, in fact, to warrant the keeping up of a proper staff of teachers.

They think, however, that the experiment is worth trying; and from what I know of the number of American medical students who yearly go abroad, I have little doubt that if Baltimore give the means for such a post-graduate course, as I am sure can be organized here, there will be no lack of candidates.

Such a medical school, it is evident, is not in antagonism to existing medical schools; it has a different purpose, and its means of fulfilling it must also differ.

The second objection made is, that the number to which the graduating class is limited is too small; that there will be many medical students who will wish to avail themselves of the special advantages of this university, and that it is bad policy to exclude any.

To this I would say, let the best man win; twenty-five students are probably as many as can be trained to the best advantage in this hospital, and what should be aimed at is quality not quantity. Some German physicians think that the course of medical instruction should occupy six or seven years, as in the new school at Geneva, or as in Sweden, taking the ground that the graduate should be master of all the resources of his art.

Without attempting to fix the precise time to be occupied in study, since some will learn as much in three years as others will in six, it does not appear to me that the purpose of this school should be to turn out finished physicians, so much as to fit men for study and investigation by themselves. For instance, I think it highly desirable that a young man intending to be a physician should learn enough of the art of drawing to enable him to note distinctly any peculiarity of form of the body, or of its organs; and if he can copy shades of color, so much the better; in part because he thus learns also to observe closely and accurately, in part because it is a powerful aid to his memory, and as a means of explanation; but I do not think it necessary that he shall be qualified to lecture *ex cathedra*, and without previous preparation, upon any medical subject selected at random, in the style that would be expected of an experienced professor.

With regard to the various medical schools which I saw, I shall here say but little, proposing to take up this subject in detail at another time. I may, however, refer to one which must always have an interest to American physicians, since it is the one which served as the model for our own, having been a century ago the most celebrated school in Europe, to which resorted those of our young men who, on their return, became the medical teachers and leaders of the New World; I mean, of course, the Medical Department of the University of Edinburgh.

This still has much the largest classes of any medical school in Great Britain, and there are several causes for this. Of these, an important one, and the one upon which most stress is laid by the Edinburgh men themselves, is the peculiar system of what are called extra-mural lectures which prevails there.

Any man who can pass a moderately severe examination, and is accepted by the University authorities, may lecture on any one subject in the medical curriculum that he chooses, and his certificate that the student has attended his lectures is of equal value before the examining board with that of the professor. He must charge the same fees that the professor does, and the students can only take a certain proportion of their tickets from the extra-mural teachers.

It might be supposed that as the professor is the examiner he would have the advantage, but impartiality is secured by placing on the examining board men who are not professors, and who are sometimes extra-mural teachers.

To obtain the degree of Bachelor of Medicine or Master in Surgery, the candidate must have studied these subjects for four years, and must have a good general education as tested by examination, or by the presentation of evidence that he is a graduate in arts. The degree of Doctor of Medicine is given two years later.

It will be perceived that a set of young professors in the shape of the extra-mural lecturers are continually in training, and that the professor himself is constantly stimulated to do his best, since he cannot fall into an easy-going jog-trot routine without soon suffering from the competition of his rivals, over whom he has some advantages, it is true, but by no means enough to enable him to rely solely upon them to retain his pupils.

In the larger medical schools of France and Germany, it seemed to me that the great clinical advantages which they present form their chief recommendation, and that the best results can only be obtained by those who go there with a very considerable stock of preliminary knowledge.

In the laboratories, physiological and pathological, of the German schools, there is for those who are fitting themselves to be general practitioners, rather too much of a forcing process in the stimulating to and requiring of some one piece of original work, instead of trying to make a man fit to undertake any original work that may present itself.

The student is led to think that his highest object should be to perform some experiment or make some observation which has never been done before, and for this purpose he may work a year in the laboratory and yet acquire but a tittle of the knowledge he went there to obtain. As a rule, it seems better that such special researches should follow and not precede general culture; if the foundation is narrow, the superstructure cannot be wide and firm.

Of buildings devoted to medical schools, I was much pleased with those at Manchester and Liverpool. Those at the latter place are all of one story, giving fine facilities for light and ventilation.

The arrangements of those at the Owens College in Manchester are also good, but they are too far from the hospital, and when there is space available, it seems to me that laboratories and lecture-rooms had better be in one-story buildings.

With regard to the vexed question of hospital construction, it seems that the majority of those who have given especial attention to this subject, prefer wards of one story, especially for surgical and obstetrical cases, and favor isolation and separation of the several buildings.

I have not found it possible to obtain positive reliable data as to the effects of various plans of existing hospitals upon the health of the inmates, except in a few special and aggravated cases. As a rule, each person thinks the system with which he is most familiar is the best; one may try to go behind the dogmatic assertions and find out upon what they are founded, but the result is negative.

Mortality statistics are of little use for this purpose, since the character of cases received varies so much. I tried at first to get the statistics of certain classes of cases, such as compound fractures and dislocations, and outbreaks of erysipelas and septicæmia—or of diseases arising among the hospital employees; but I

was soon convinced that these depend far more on methods of management and treatment, on the preservation of cleanliness, and on care in the use of antiseptics and disinfectants, than on the plan of the hospital; and that where what is known as "Lister's method," is regularly and methodically employed in the hospital, its healthfulness cannot be estimated by the statistics of the surgical wards.

I was acquainted with Mr. Lister's teachings before visiting Europe, and assented to them in a theoretical sort of a way; but at the same time I looked upon the antiseptic method as being the latest fashion, and therefore probably overpraised. But after learning the results of its employment in the hospitals at Bonn, Leipzig, Berlin, and in certain wards in London, and especially after an examination of Mr. Lister's wards in the Royal Infirmary at Edinburgh, and seeing the cases dressed in all stages after operations—operations such as opening the knee-joint, or upon abscesses of spinal origin—I came to the conclusion that this method is the most important contribution to our resources in surgery which has been made since the discovery of anaesthesia. Not that the details of the method are perfected, for probably much may yet be done to simplify it, and we may perhaps discover a better material for the purpose than carbolic acid; but we now may be said to know positively, instead of merely conjecturing, that the process of putrefaction is due to minute solid or semi-solid particles floating in the air, and that Mr. Lister has devised a method by which these particles can either be kept out of a wound made by the surgeon, or by which they will have their power of producing the putrefactive change destroyed, is, I think, beyond doubt.

The fact that the various changes in organic matter which we know as fermentations, putrefaction, etc., are due to minute organisms, which organisms are not spontaneously developed, but arise from similar organisms only, is one of great importance in hospital management.

Perhaps you are not all familiar with the exceedingly careful, minute, and laborious researches which Mr. Lister has made on this subject of the germ theory, and the development of bacteria, and I would therefore call your special attention to papers published by him in the Transactions of the Royal Society of Edinburgh for 1875, and the *Microscopical Journal* for 1873. I had the opportunity of examining his specimens and apparatus, including some of which he has not yet published a description, and from these, from the clinical results obtained by him and by those who have properly used his methods, and from the researches of Dr. Burdon Sanderson on Contagion, and of Tyndall and others on Dust, I think it may be considered as certain that the dangerous thing in a hospital is a dust, an excessively fine, organic dust, which is almost omnipresent, which is in the air, the bedding, the hair, and the clothes of all occupants of the buildings, and the particles of which are so minute, and have so low a specific gravity, that their rate of fall through the air when it is perfectly still, may not exceed two inches per hour.

Some of these particles are living organisms, spores of fungi, bacteria, microzymes, of various kinds, some vegetable, others animal in character.

These living organisms when first produced, and in a state of activity, are more or less gelatinous in consistency, and will adhere to any surface with which they come in contact. While in this condition, they are not found in the air to any great extent, but exist in fluids, discharges, and moist places. In this condition they can be filtered out from the fluids which

contain them, and these fluids thus filtered, lose their specifically dangerous qualities. They soon dry—at least on the surface, and in this condition lose their adhesiveness, and are easily detached and carried about by currents of air. To enable them to develop and multiply and reproduce their kind, which they sometimes do with amazing rapidity, there is necessary the presence of moisture and of organic matter. For our purposes, we may divide these living organisms or microzymes into two classes.

The first includes the ordinary forms which are found everywhere, and which are the efficient causes of mould and mildews, and of fermentations and putrefactions. Under ordinary circumstances we know that these are not dangerous. We can hardly draw a breath without inhaling them; we cannot take food, or water, or milk, without swallowing them. It is believed by Mr. Lister that healthy living tissues are capable of preventing the development of these low organisms in their immediate vicinity.

This is perhaps doubtful, unless by immediate vicinity is meant actual contact, but it is certain that unhealthy tissues and fluids in the body may favor their development. In these unhealthy tissues, these common forms appear sometimes to acquire new and specific powers by successive development, so that it is possible to produce from common harmless forms, by successive inoculations, other forms which act as specific morbid poisons in a healthy organism.

The second class of microzymes includes those which are not everywhere present, but for the most part arise only in diseased men and animals, and appear to have the power of producing diseased action even in perfectly healthy tissues. These constitute what is called contagium, and are what we have in mind when we speak of the germ theory of disease.

All problems of isolation and disinfection in a hospital have reference to these contagia only, for there is no isolation or disinfection which will rid us of the microzymes of the first class.

The vitality of these germ is destroyed by a dry heat of 240° F. continued for three hours, and upon this fact is based the principle of the disinfecting ovens and stoves, which are coming more and more into use in Europe, and especially in Great Britain. A careful series of experiments on this subject has been made under the supervision of the medical officers of the local Government Board, with the result of especially approving a form in which the heating is effected by gas, and the products of combustion are allowed to pass into the heated chamber. The results which have been obtained from the use of these ovens in Great Britain, and by the methods of disinfection employed under the direction of the Boards of Health of New York and New Orleans, fully warrant the conclusion that we can destroy these minute germs in clothing, in bedding, and in habitations. Besides these microzymes we have also, in a hospital ward, other particles of organic matter, not living, derived from the surfaces of the skin and mucous membranes, and especially from the mouth and air-passages during respiration, which are important as furnishing nutriment and means of development to the microzymes above mentioned.

Perhaps, although with our present knowledge we can hardly say that it is probable, we may also have in the ward certain complex vapors or gases of organic origin which are dangerous. It rarely occurs that in any ward there are enough of the known poisonous gases, such as sulphuretted hydrogen and carbonic oxide, to produce poisonous effects, and I presume that I need hardly assure you that that great bugbear,

carbonic acid, about which popular lecturers on ventilation discourse so learnedly, is never a dangerous impurity in a hospital. I saw, however, two hospitals in Europe where openings had been made from the ward to the external air at the level of the floor, in order "to let the heavy gases, and particularly carbonic acid gas, run off." As there are no heavy gases near the floor in any greater proportion than there are at the ceiling, it is clear that the result desired could not be obtained.

It is curious to note how widely spread are the fallacies that carbonic acid is the dangerous impurity to be got rid of by ventilation; and that as it is heavier than ordinary air, it will sink towards the floor and be found there in increased proportion. These fallacies are usually urged by those who advocate a downward system of ventilation; the law of the diffusion of gases, and the actual effects of carbonic acid on the animal system being apparently unknown to them. The question assumes a different aspect when we know that the dangerous impurity is particulate or a dust. This is slightly heavier than the air, but settles very slowly, and is carried up by very feeble currents. Probably, however, it will be found in greatest quantity near the floor; but the difference is not very great.

In a hospital ward properly managed, the object, so far as purity of the air is concerned, should be as follows: First, to prevent the development of any of the contagious germs in the ward by not admitting to it patients whom we have reason to believe are producing them; or, where this is impossible, by destroying their vitality while yet in the moist condition.

This involves isolation, and the methodical use of antiseptics and disinfectants in connection with all excreta and discharges. It also involves keeping the wards, floors, and walls as dry as possible. New hospital wards in brick buildings are very apt to be unhealthy, and this seems to be due to excess of moisture in the walls. When the new building for the Royal Southern Hospital at Liverpool was occupied by patients, the results for the first year or two were not as good in the fine airy pavilion wards, in which each man had 2,000 cubic feet of air space, as they had been in the old crowded building which had been previously occupied. Erysipelas and other hospital diseases appeared; and not until the thousands of gallons of water, which the new bricks and mortar contained, were removed by the slow process of evaporation, did the building become a healthy one.

The second object in hospital management is the removal of all dust which has settled or lodged, and that this shall be a real removal, and not a mere scattering of it from one place to allow it to settle elsewhere. If, for instance, dust is removed with a damp cloth, this damp cloth becomes a dangerous thing in itself. If the external air be cold, we may have a precipitation of moisture on the glass of the windows, and in this moisture will be a considerable proportion of organic matter, so much that if it be collected the fluid will give decided signs of putrefaction.

Now this precipitation of moisture and organic matter is temporarily a purifying process; but if the windows be allowed to dry of themselves, we have, then, a store of dangerous dust, on and at the bottom of the panes, which must be taken care of. I might go on in like manner with many other details, but I have said enough to show what is required.

I came back more thoroughly impressed and convinced than ever, that the thing of prime importance in a hospital, is minute care of, and cleanliness in, every part and person about it, and in the management

which will insure this; while without it the most perfect structure that can be devised, soon deteriorates, and gives only second or third rate results. It was very interesting to observe how, in some of the older hospitals, such as the Rotunda in Dublin, Guy's and St. Bartholomew's in London, the City Hospitals in Bonn, in Leipzig, and in part of the Charité in Berlin the defects of construction and plan were compensated by the mode of management; while, on the other hand, in hospitals admitted to be much superior in plan, such as the Lariboisière, St. Thomas's, and the Herbert, in which it had been apparently supposed that they were so perfect that it did not matter how they were managed, the results are by no means so satisfactory.

The third point in ward management is ventilation; and with regard to this, I am sorry to say that I was able to obtain but little positive information as to the relative economy of the various methods—which is, after all, the main question in dispute.

There, as here, opinions for which no precise data could be given, were abundant; but when I asked how much fresh air is introduced into this ward in an hour? how well it is distributed? and how much does it cost? it was only in two or three hospitals that I could get any definite answers.

The data obtained from English hospitals are of little use to us in this country, owing to the marked difference in climate. Even in England, large wards are not, as a rule, sufficiently heated to make the patients comfortable; and I found that various methods were being tried to supplement the open fire-places, which are not satisfactory, and yet whose efficacy it is considered almost criminal to doubt. Open windows, and various valves and contrivances to throw the incoming cold air upwards are employed; and of these, if open fire-places are to be the sole means of heat and ventilation, and the incoming air is not to be warmed, I think that what are called Tobin's tubes are the best. A modification of this principle is used in the new wards in the London Hospital, in which the fresh air is taken in through slits in the window sills, and this mode is also employed in the new New York Hospital, but the air is warmed before admission.

In the latest and best of the German hospitals, the principle has been adopted of making the heating and ventilation of each building independent of every other. The results, as I observed them, were good, but the arrangements are complicated and expensive, and require careful superintendence. The principal authorities whom I consulted, prefer systems of aspiration to those of impulsion, but are of the opinion that although it may be theoretically possible to effect ventilation of an extensive and scattered series of building by means of one great aspirating chimney, yet that the practical difficulties in the way of adjustment of ducts and apertures to secure in all parts the flow of air desired, will be so great, that it will not be prudent to attempt it.

There is a general feeling of timidity about attempting to use large and powerful but complex systems, which is due to sad experience of failures of such, and hence the recommendation to heat and ventilate each building by itself, or, in other words, to give up the problem of concentration and simplification of the apparatus as unsolvable.

I found the fan or impulsion system in use with good results in the Grand Opera House in Vienna, with medium results in the Chamber of Deputies at Versailles, and with poor result in the Gynæcological Hospital at Bonn, and in the "Lariboisière" and "Necker" in Paris.

Where it was a failure, it was easy to see that the

ducts and fans were improperly arranged and were insufficient in size.

It is my opinion that those who condemn the fan do so for want of experience with fans and ducts of the proper size, and that the results that have been obtained with it in some of the large hospitals for the insane in the United States, and in the "Barnes Hospital" at Washington, are such as to warrant the statement that during the warmer half of the year it is the better and cheaper mode of ventilation.

I have not time here to go into these questions, which indeed are of interest to architects and engineers rather than to physicians, and will only say that what is required is, that at least one cubic foot of air per second, per bed, shall be introduced, thoroughly distributed, and removed in each common ward and payward; that in the isolating rooms, the capacity should be for double this amount; that this must be done without producing drafts or currents that will be so perceptible as to cause discomfort; and that it must be done in still warm days as well as in cold windy ones.

Now bearing in mind what I have said to you about the dangers of organic dust, I prefer that this dust should be drawn down rather than up, and if it is to travel along flues to any distance I should have them so constructed that they can be cleansed by fire occasionally.

If the openings of the foul-air ducts are near the ceiling only, a thorough distribution of the fresh incoming air is made very difficult, and indeed requires that the fresh air registers should be scattered over the whole floor. In a theoretically perfect ventilation, the whole mass of air in the room should move either directly upwards or downwards at the rate of not less than one inch per second, but this is out of the question in most cases, since it would require over eight cubic feet per second, per man, if we allow 100 square feet to each bed.

If the direction that the nurse should "never be satisfied unless she can feel the air gently moving over her face when she is still," were to be carried out, it would require about 50 cubic feet per second, per man; or if the upward movement were to be maintained, it would require nearly 200 cubic feet per second per bed.

Now supposing that the three objects to which I have referred have been well carried out, it is probable that the danger of hospitalism would be greatly diminished, because we should have gotten rid of most of these specific germs. Even this danger would not be entirely removed, however, and we should still have abundance of the causes of ordinary putrefaction in the ward. We cannot therefore afford to neglect the means of preventing these causes from gaining access to wounds, and the means proposed by Mr. Lister should be used until a better one is given.

It is a great error to suppose that the antiseptic method can take the place of good hospitals and good management; this ought to be done, and the others not left undone.

## AN INTERESTING CASE OF STRANGULATED BUBONOCÆLE. HERNIOTOMY.

RUPTURE OF THE INTESTINE DURING REDUCTION—  
CLOSURE OF WOUND WITH LEMBERT'S SUTURE—  
RECOVERY.

By JAMES L. LITTLE, M.D.,

OF NEW YORK;

PROFESSOR OF SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF VERMONT AT BURLINGTON, VT.; ATTENDING SURGEON TO ST. LUKE'S AND ST. VINCENT'S HOSPITALS, N. Y., ETC.

While delivering the annual course of Lectures on Surgery, at the Medical Department of the Vermont University, in June, 1875, I was called in consultation by Dr. H. H. Langdon, of Burlington, in the following interesting case of strangulated hernia.

Edward Walsh, aged forty. Native of Ireland; laborer; of intemperate habits. He stated that he had had a rupture on the right side for about six years. He had always been able to reduce it with ease, and had never worn a truss. On May 25th, it became strangulated while at Westport, N. Y. A physician was called, who reduced it. He came over to Burlington, Vt., and, May 28th, sent for Dr. Langdon, who found him suffering from a strangulated inguinal hernia. The tumor was situated over the external ring and had not descended into the scrotum.

The doctor, after some manipulation, apparently reduced the hernia. The symptoms—vomiting, severe pain in region of the umbilicus, and constipation—still persisted. Cathartics and enemata were administered, but no action of the bowels was obtained. On June 2d, five days after the apparent reduction of the hernia, I was called in consultation. I found the patient suffering from constant hicough and vomiting; abdomen distended, tympanitic, and tender on pressure, the tenderness more marked in the right inguinal region; the pulse was small and rapid. No tumor could be seen or felt in the place where the hernia had existed. A more careful examination, however, discovered an indistinct hardness over the situation of the right internal abdominal ring. This could be determined only by extending the thighs so as to put the parts on the stretch, and placing one hand over the situation of the right internal ring, and the other over the left, and rubbing the integuments over the subjacent parts with both hands at the same time. In this way a deeply-seated swelling, like an enlarged gland, could be indistinctly felt. This, I suspected, was a portion of the contents of the hernial sac remaining unreduced and strangulated in the inguinal canal. I at once advised that an explorative operation be performed. About two hours later the patient was examined, at my request, by Dr. Wm. Darling, of New York, Dr. A. F. A. King, of Washington, and Dr. Walter Carpenter, of Vermont, professors in the medical department of the University. On the first examination they were unable to appreciate the existence of any tumor or swelling, but by examining both sides at the same time, as described above, they were able to detect a deeply-seated swelling over the right internal ring. They agreed with me in advising an explorative operation. To this the patient consented.

*Operation.*—Present, Professors Darling, King, and Grinnell, and a number of the students of the University. The patient was etherized by Dr. Langdon. The pelvis was slightly elevated and the thigh extended. An incision about two and a half inches long was then made just above and parallel with Poupart's ligament, and over the internal abdominal ring.

AMERICAN MICROSCOPICAL SOCIETY.—At the Annual Meeting of the American Microscopical Society of the City of New York, the following officers were elected for the ensuing year: *President*, John B. Rich, M. D.; *Vice President*, Wm. H. Atkinson, M.D.; *Secretary*, O. G. Mason; *Treasurer*, T. d'Oréaniculx; *Curator*, John Frey.

The various layers were carefully divided until the fibres of the internal oblique muscle were reached. On examination with the finger, at this stage of the operation, no tumor could be detected, and it was suggested by those present that the internal oblique be not divided. Thinking it better, however, I cut through the fibres of this muscle, and at once a tumor, the size of a small hen's egg, made its appearance. The transversalis fascia and the peritoneum were then divided, and a knuckle of the small intestine came into view. It was of a very dark color, but the odor was not unpleasant. The fluid in the sac was also discolored. On further examination the seat of the stricture was found to be the internal abdominal ring. With some difficulty I succeeded in passing my finger through the ring, and with the hernia knife divided the constriction. The intestine was now pulled out so that the part engaged in the stricture could be examined. The dark color of the gut slowly disappeared, except in two or three spots situated on that portion of the intestine which had been engaged in the ring. A considerable quantity of serum made its escape from the abdominal cavity through the wound.

On attempting to reduce the intestine, one of these dark spots, which was evidently gangrenous, ruptured, and a stream of the liquid contents of the intestines, the size of a knitting-needle, spurted out over the gut and surrounding parts.

This small opening was at once seized with a pair of artery forceps, but the portion included in the teeth of the forceps came away, enlarging the opening to the size of a No. 3 bougie. A second attempt, taking up a larger portion with the forceps was more successful, and arrested the escape of the contents of the intestine.

The moment the rupture took place, I immediately put a towel around the protruding gut and over the wound to prevent the intestinal matter getting into the abdominal cavity.

The flow of serum from the peritoneal cavity also contributed toward preventing this accident.

The wound in the intestine was then closed with Lembert's suture. With a lady's sewing-needle and fine silk, three sutures were applied. These, however, were placed too near the opening, and as soon as an attempt was made to reduce the gut they gave way, and again the intestine and parts around were covered with the contents of the alimentary canal.

Four new sutures were then introduced outside of the others, so as to include and curl in the entire dark spot, the first sutures remaining. After the sutures were tied, a deep indentation, about one inch in length, parallel with the gut, was the result. The intestine and surrounding parts were then carefully

cleaned with warm water. A disinfectant was not on hand and could not be obtained in time.

My hands were also thoroughly cleansed, except from the disagreeable odor, before attempting the reduction of the intestine. This was accomplished without difficulty.

The wound was then closed with interrupted sutures, and a compress and spica bandage applied.

Ordered gr. i. of opium every two hours after the patient had fully recovered from the effects of the ether.

June 3.—Dr. Langdon reports that patient has had four free movements from the bowels during the night. No vomiting, the abdomen soft, and in every respect patient much better.

June 5.—Opium continued at intervals of three or four hours. He had a free movement of the bowels during the day. Hiccough has ceased. Tympanitis almost entirely disappeared.

The wound was examined on the fourth day, and a stitch or two removed to permit the escape of a slight accumulation of pus. The wound was then dressed with a compress, wet with a weak solution of carbolic acid. Milk and beef tea were administered the first few days after the operation.

The patient was able to present himself at my clinique, at the College, two weeks after operation, with the external wound almost healed.

The discharges from his bowels were carefully examined during the time that the patient was under treatment, but no traces of the sutures were found.

The form of the suture used in closing the wound of the intestine is represented in the accompanying woodcut (Fig. 1). Fine silk and a lady's small sewing-needle should be used; this needle doing less injury to the tissues, and causing less hemorrhage than the ordinary surgical needle. The mucous membrane should not be included in this suture. When the sutures are tied, the lips of the wound are inverted and the serous surfaces of the intestine are brought in contact, as represented in Fig. 2, and readily unite. The sutures find their way into the intestinal canal and are expelled with the feces.

The value of this suture for wounds of the intestine can be readily demonstrated. A wound an inch in length, made in a piece of intestine can be closed with four of these sutures so tightly, that no air will escape, even if the gut be fully distended.

## Progress of Medical Science.

CARBOLATED CAMPHOR AND ITS USE AS A SURGICAL DRESSING.—Dr. Soulez, of Romorantin, recommends this substance very highly. He prepares it by mixing 1 gramme of carbolic acid (solution of 9 gm. acid to 1 gm. alcohol) with 2½ gm. of powdered camphor. The product is an oleaginous pale-yellow liquid, with a feeble odor of camphor, and no odor of carbolic acid at all. It does not mix with water or glycerine, but does mix with olive and almond oils. The infusion of saponaria (100 gm. of the leaves of soapwort to 1,000 gm. water) emulsifies it, as does also the alcoholic tincture of *quillaria saponaria* (alcohol at 90°, 1 litre; Panama bark, 250 gm.). When mixed with an equal part of the carbolated camphor, this tincture produces a mother emulsion, which, when weakened with water, is used to prepare the antiseptic wadding.

In dressing a wound, Dr. Soulez covers it first with

a square of wadding, which is impregnated with a mixture of carbolated camphor and olive-oil. This must be large enough to extend  $2\frac{1}{2}$  to 3 inches beyond the wound. This is then covered by six other layers of wadding, impregnated with the emulsion above mentioned. Each layer should be one inch wider than the one below it. A thin envelope of caoutchouc is then applied to prevent evaporation, and over this a layer of dry wadding, and the whole is then secured by a bandage. The author claims that this dressing is very easy of application; all the materials can be prepared beforehand, and kept in well-covered jars. Before applying it the wound should always be washed with the emulsion of carbolated camphor. The dressing possesses all the advantages and none of the inconveniences of Lister's method. When applied to a stump, for instance, it keeps it enveloped in a warm atmosphere saturated with vapor of water, which lessens the exciting effects of the oxygen of the air, and is protected by the numerous layers of soft wadding, which keep out all infecting germs. Dr. Soulez renews the dressing usually every six days, but sometimes leaves it on for ten days. So far he has never known the carbolated camphor to cause the least irritation of the skin or the wound. When the caoutchouc is removed, all the layers of wadding are found to be as moist as when first applied. He claims to have obtained the following advantages from the use of his dressing:

1. Lessening of the reaction after major operations.
2. Cessation or diminution of the pain.
3. Diminution of the suppuration. — *La Tribune Médicale*, Dec. 24, 1876

EXPERIMENTAL INVESTIGATIONS OF THE FUNCTIONS OF THE BRAIN.—Prof. Nothnagel, of Jena, reports the following as the results of his efforts to discover the functions of the cerebellum:

1. The cerebellum presides over muscular co-ordination; its function is therefore to a certain extent of a motor character. This influence on co-ordination can be demonstrated both by irritating and by destroying the organ.
2. It is exceedingly probable that there is a very intimate functional, and consequently also anatomical, connection between the two halves of the cerebellum.
3. The complete destruction of parts of the cerebellum, the irritation of which produces decided but temporary motor effects, causes no manifest "loss of co-ordinating power" (Goltz).
4. The destruction of one hemisphere or of both hemispheres alone, or of the anterior and upper part of the vermiciform process alone, produced no disturbances of co-ordination. On the other hand, mechanical irritation of these parts excited motor manifestations of irritation.
5. The well-known disturbances of co-ordination are excited only by an injury which affects at the same time the deeper parts of both hemispheres and the vermiciform process.

Prof. Nothnagel thinks that Schiff's assertion that nothing at all is known of the functions of the cerebellum is not tenable. The above statements demonstrate that the mass of the organ, in its entirety, has some connection with the power of co-ordinate movement. — *Ally. Med. Cent. Zeit.*, December 20, 1876.

SECONDARY HEMORRHAGE AFTER THE USE OF ESMARCH'S BANDAGE.—Prof. Esmarch thinks that the severe secondary hemorrhages after amputations, and the frequent hemorrhages after other operations in which his bandage is used are attributable, in many

cases, to the use of too firm a constriction. The rubber tubes usually employed are too thick and hard, and too much force is exerted in applying them. The necessary consequence is a complete paralysis of the vasa-motor nerves, and hence obstinate hemorrhage after the removal of the tube. For some time past Prof. Esmarch has only used the tube in operations at the shoulder and hip-joint, and has found that he can obtain quite sufficient constriction in other operations by means of the elastic bandage alone.

Another cause of these secondary hemorrhages is the imperfect means employed to check the bleeding after operations. In operations for necrosis, Prof. Esmarch, before loosening the constricting band, fills the cavity in the bone, which he always makes trough-shaped, with charpie that has been soaked for a long time in carbolic acid, and applies Lister's antiseptic dressing. If the dressing is well applied, not a single drop of blood will ooze through it after the tube is removed. The charpie is left *in situ* for several days. In resections the tube is loosened before the wound is dressed, and all spurring arteries are tied. In amputations Prof. Esmarch lays great stress on the importance of a circular cut through the muscles, so as to avoid cutting the arteries obliquely. When the limb is removed he seizes the gaping vessels one after another with bulldog forceps, which he leaves hanging to the stump until he has secured every vessel that he can see, and he then ties them with catgut ligatures. He applies the ligature to both arteries and veins, and believes that when the veins are ligated the danger of secondary hemorrhage is greatly diminished. The rubber tube or constricting bandage is then removed as rapidly as possible; if it be gradually loosened the hemorrhage will be great, because the blood will be pumped into the arteries, but will be unable to flow back through the still constricted veins. He then takes an irrigator filled with a weak solution of carbolic acid, iced, and douches the surface of the wound. The smaller vessels that still bleed are in this way easily seen, and seized with forceps, which are left hanging to the stump. When no more bleeding vessels can be seen, he proceeds to secure those that have been found with catgut. If the operator wait to tie each vessel as he seizes it, much time and much blood will be unnecessarily lost. Prof. Esmarch always has from thirty to forty pairs of forceps on his operating table, and all of them are sometimes in use before he begins to apply the ligatures.

Finally the iced douche is kept up until the capillary hemorrhage ceases, and the stump may then be dressed without fear. For several years none of his amputations or other capital operations have been followed by secondary hemorrhage.

REGENERATION OF THE PNEUMOGASTRIC NERVES.—At the meeting of the *Société de Biologie* in Paris, on December 9, 1876, a paper by M. Philippeaux was read, in which the results of some experiments, undertaken to prove that complete re-establishment of the tissue and functions of a nerve may take place after its division, were detailed. He found that sixty days were required for the re-establishment of the functions of the pneumogastric nerve in the dog, and eighty days for that of the guinea-pig. In some white mice he found that the re-establishment of function was nearly completed in thirty days. On examining the divided nerves in these animals at the end of thirty days, he found the union complete; only a few of the primitive tubes still presented traces of alteration, or were in process of regeneration. There were still slight enlargements at the extremities of the divided

ends, the enlargement of the cerebral end being more voluminous than that of the peripheral end.—*Gazette Médicale de Paris*, Dec. 30, 1876.

**CHANGES IN THE FORM OF THE HEAD OF THE CHILD DURING LABOR.**—The elongated, pear-shaped form of the head, when the vertex has presented, and the flattening from above downwards after presentations of the face, have long ago been noticed. These changes in shape are characteristic and independent of any contraction of the pelvis. At the end of twenty-four or forty-eight hours after birth, the head has reassumed its normal rounded shape. M. Budin has made numerous mensurations and drawings during the first eight days after delivery, and he shows that the peculiar anatomical conditions favor these changes of form. In the first place, he has found that the occipito-mental is not the longest diameter of the head, the longest being the diameter extending from the chin to a variable point between the occipital prominence and the anterior fontanelle. On the first or second day after birth, the occipito-mental, occipito-frontal, and suboccipito-bregmatic diameters have all increased in length by one fifth of an inch, and as the head at this time has resumed its normal form, it is rational to conclude that these diameters were shortened during labor. The maximum diameter, on the contrary, diminishes in length during the first and second days of life; hence it must have lengthened during labor.

In examining the cranium of a still-born child, if the two parietal bones be removed, the entire occipital portion of the occipital bone will be found to be very movable, and its superior angle can be pressed forwards; a sort of hinge, composed of fibrous and cartilaginous tissue, exists between the occipital and basilar portions of the bone. During labor the superior angle of the occipital bone is pushed forwards under the parietal bones, and hence the occipito-mental and occipito-frontal diameters are shortened. The superior border of the frontal is thin and supple, and is also depressed, and hence the suboccipito-bregmatic diameter is shortened. The parietal bones are compressed from before backwards, and their sagittal border becomes more convex, and hence the maximum diameter is elongated.

The phenomena are different when the face presents. The superior angle of the occipital bone is pushed backwards, and consequently the occipito-mental and occipito-frontal diameters are increased. The head reassumes its normal form, and the diameters diminish after birth. Consequently the same anatomical arrangement explains entirely different deformations.

After the head has regained its normal form, it begins to increase in all its diameters, provided the child be healthy.—*Lyon Medical*, Dec. 24, 1876.

**LOCOMOTOR ATAXIA OF SYPHILITIC ORIGIN.**—The fact that locomotor ataxia sometimes attacks persons with a syphilitic history has been noticed by many authors, but hitherto this concurrence has attracted but little attention. In a series of lessons which have been recently published, M. Alfred Fournier, however, maintains that there is a relation of causality between syphilis and *tubus dorsalis*. In thirty cases of ataxia that came under his observation, he obtained histories of antecedent syphilis in twenty-four. M. Péréal found that five out of his eleven cases of ataxia had previously suffered from syphilis, and M. Sindy in ten cases of ataxia found syphilis eight times. These statistics are of course too few in num-

ber to allow us to base any certain conclusions on them, and even M. Fournier would hardly maintain that the proportion of cases of ataxia, which are of syphilitic origin, is as high as the above figures would make it. Still it would be irrational to suppose that chance alone could explain so frequent a coincidence. It is necessary to admit a more or less intimate connection of the two morbid conditions, a dependence of one on the other. The influence of syphilis on the development of ataxia would seem to be similar to that of rheumatism on endocarditis, or of blennorrhagia on blennorrhagic rheumatism.

Several objections have been raised as to M. Fournier's theory. One of them is that the supposed syphilitic ataxia presents no special symptoms, and another that it presents no special lesions. M. Fournier answers the first by pointing to the fact that syphilitic paraplegia, syphilitic cirrhosis, etc., present no special symptoms, and still their specific origin is questioned by none; and the second by the statements that many common lesions are attributed by all authorities to syphilis, and that, moreover, the sclerosis of the posterior cords, which characterizes ataxia, is very similar in nature to the usual lesions of tertiary syphilis. In six of his cases, M. Fournier obtained great benefit from the use of anti-syphilitic treatment. Of course, in advanced cases, in which the disorganization of the posterior columns of the cord is almost complete, no treatment will be able to reconstruct the destroyed nervous elements.

The symptoms and course of syphilitic ataxia are similar to those of the ordinary form. At the most, in the former, the cephalic symptoms are less frequently the initial phenomena of the affection. Incomplete cases are met with in both forms. M. Fournier distinguishes three types of the affection, viz., the lumbar or spinal, the cephalic, and the ocular (tabetic amaurosis). It is an interesting fact that the syphilitic ataxia is rather often accompanied by other specific affections of the nervous system, such as hemiplegia or paraplegia. M. Fournier terminates his brochure with the following conclusions:

1. In every case of ataxia it is the duty of the physician to examine carefully for traces or the history of syphilis.

2. If an antecedent syphilis have existed, or be even suspected, the primary indication is to prescribe the treatment of that diathesis. Experience teaches that this treatment has several times produced excellent results, and the plain duty of the physician is to give the patient the benefit of the chance.—*Gazette Médicale de Paris*, Dec. 30, 1876.

**PARTIAL APHASIA WITHOUT APPRECIABLE LESIONS OF THE ISLAND OF REIL.**—Professor Wood, of Philadelphia, reports a case that is interesting in view of two points: one, that there was no choked disk in local and general meningitis, and the other, the presence of aphasia without any apparent alteration of the island of Reil. The absence of choked disk does not, in Dr. Wood's experience, indicate the non-existence of cerebral growths, or even of meningitis. Nor does the condition of the island of Reil disprove the theory of speech localization, for though the macroscopic and microscopic characters of the part did not show any decided change, the meninges over it were thickened, and as they supply it in part with vessels, there may have been an impediment to the circulation sufficient to constitute a functional disturbance, while the actual structure was not sufficiently altered to be determined by the present methods of examination.—*Am. Journ. of the Med. Sci.*, Jan., 1877.

## PUERPERAL FEVER IN CHARITY HOSPITAL.

It is unfortunate to find that puerperal fever has again appeared and been the cause of several deaths in Charity Hospital during the month of January. What calls for grave censure is that the obstetric service has been conducted in the general hospital, where nearly every form of disease finds a home, with the exception of eruptive fevers. It might have been expected when the transference of parturient and pregnant women took place from Bellevue Hospital, in the summer of 1874, that eventually something had been learned in regard to the proper treatment of obstetric cases, particularly when, in the following year, during the discussion at the County Medical Society of the genesis of the last puerperal epidemic at Bellevue, the error of continuing the service in the wards of a general hospital was fully indicated. Aside from this, the results obtained in stamping out the disease after the patients had been conveyed to Blackwell's Island were amply sufficient to gratify all who take an interest in the prophylaxis of puerperal disease.

Regardless, however, of the experience of the past, and of the admonitions of those who spoke knowingly on the subject, the old routine has been resumed, with a result corresponding to what might have been anticipated.

If there is one thing at present settled in regard to the treatment of these cases, it is that delivery should take place in structures of such a character as can be readily destroyed when any epidemic appeared, and that these structures can be completely isolated, not only from all surgical cases, but even from medical cases, for professional experience has not yet decided how far acute medical disease may act as a factor in generating some of the forms of puerperal fever.

These precautions were not taken at Charity Hos-

pital, and, whilst it is our duty as an exponent of the profession to draw attention to the neglect, we are not in a position to say whether the responsibility rests with the Medical Board, in not advising the proper procedures, or with the Department of Public Charities and Correction, in not carrying out such advice, if it were given.

## THE HEALTH BILL FOR THE STATE OF NEW YORK.

The new Health bill now before the Legislature is one which deserves the active support of the profession throughout the State. It embodies the suggestions of the standing committee on Hygiene of the New York State Medical Society in conjunction with the most effectual practical measures of other States which have such boards.

## DRUGGISTS' WEIGHTS.

SENATOR WAGSTAFF has recently introduced into the Senate a bill for the purpose of regulating the weights and balances used in compounding and dispensing drugs and medicines in the city of New York. The bill provides that druggists shall employ proper balances and weights, and indicates the limit of inaccuracy that will be permitted. They shall also be provided with a set of Metric weights. Troy and Metric shall be the only weights used in compounding and dispensing medicines. This is rendered necessary by the fact that in probably ten per cent. of the drug stores in this city there are no Troy weights. The bill also provides for an inspector to carry out the law. Inaccurate weights will be confiscated, and their owners fined ten dollars. There will be no charge for the inspections where everything is found right. It is to be hoped that this bill will pass, as the present scandalous condition of affairs should be speedily remedied.

## SANITARY INSPECTION OF SCHOOLS.

SINCE we took occasion to refer to the bill of Senator Gerard for the creation of the office of Sanitary Inspector of Schools, we have learned that the Board of Education of this city have seen fit to oppose the measure. We confess that this action is somewhat astonishing. The following is the remarkable resolution passed at a recent meeting:

*Whereas*, It is reported in the public journals of this date that Senator James W. Gerard has introduced a bill in the Senate of this State to provide for the sanitary inspection and supervision of the public schools in this city by creating an additional and useless office, to be filled by the Board of Education for that purpose; therefore,

*Resolved*, That this Board respectfully protests against the passage of any such law as unnecessary and uncalled for by the public interests or welfare of the public schools of this city."

It is difficult, in the face of the overwhelming proof

in favor of sanitary inspection of our public schools, to speak with calmness of the impudence and stupidity which prompted this objection. Senator Gerard, in expressing his surprise at the passage of the resolution, very significantly says that he would have been much better satisfied with the reasons of the Board than a simple protest.

It will be a matter of great curiosity with the medical profession of this city, and with all sanitarians, to know what these reasons may be. We almost expect to hear that the schools are not overcrowded, that the ventilation is perfect enough for all practical purposes, that the danger of propagating infectious diseases is a myth, that cellar class-rooms are healthy—in fact, that no other persons are privileged to have any opinions upon these questions save the oracles of the Board. Indeed, we have good reason for supposing that such an anticipation of their line of argument has some foundation in actual fact. The school inspectors of the Fifth District have saved us from some of the possible flights of imagination by a few curiously significant statements. These are so confidently made that it would be an insult to common sense if we doubted the authority upon which they are based. These inspectors are now able to declare that they have “no doubt that the health of the children is promoted by their attendance, study, and discipline in our public schools,” and consequently we presume “it is unnecessary that a physician should be appointed to look after the health of the children while attending schools.” Further, in view of the foregoing facts, they “are of the opinion that the children when ill should be visited by physicians at their homes.” If we have not done full justice to these gentlemen in presenting their argument in this shape, it is not from any lack of desire to strain a point in their favor. In fact, we dignify their report by a notice, for the reason that it is the best explanation which they have given in the minutes of the Board for the passage of what might otherwise be considered a very stupid resolution.

To be as serious, however, as the circumstances of this ludicrous action on the part of the Board will allow us, we ask if it is not time that a fitting rebuke should be administered. It strikes us that the only reasonable way to explain the course taken is an impudent defiance of public and professional opinion. Senator Gerard is just now in a position of great responsibility, but he can rest assured that his advocacy of the bill will be sustained by popular and professional sentiment not only in the city, but throughout the State. We believe him equal to the occasion, and hope for the best.

**METRIC SYSTEM.**—The Syracuse Medical Association, at a late meeting, resolved to recommend to its members the use of the metric system in prescriptions, and in all communications in which reference is made to weights and measures. Some of the druggists have already taken measures to supply themselves with metric weights.

## Reports of Societies.

### NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, February 15, 1877.*

DR. S. S. PURPLE, PRESIDENT, IN THE CHAIR.

#### THE RELATIONS BETWEEN PSEUDO-MEMBRANOUS CROUP AND DIPHTHERIA, AND THE VALUE OF TRACHEOTOMY IN EACH.

DR. JOHN C. PETERS opened the discussion by giving a brief outline of the history of diphtheria in the United States. In the history of New England, by J. Joslyn, Gentleman, in the years 1638 and 1663, the malady was referred to under the general description, “fearful disease in the throat, which proved fatal in a short time.”

In a history of New England, prepared by Morse and Parish in 1804, reference was made to a most extensive epidemic of “throat distemper” which occurred in the year 1735. Dr. Douglas’s paper of 1735 was also attached to Caspar Morris’s paper upon scarlatina. Bard described diphtheria in 1771.

In Vermont, from the year 1773 to 1777, it was known by the name, “malignant sore-throat;” in 1778 it was described as cynanche trachealis, or croup; in 1793 as malignant sore-throat; in 1795 as “anginal epidemic;” and in 1796 as ulcerous sore-throat.

In the latter year it was said that some cases exhibited a rash having a crimson appearance; in others there was no eruption; probably there was a mixture of scarlet fever and true diphtheria. In 1802 and 1803 it again appeared in Vermont, and was called the “throat distemper;” in 1810 it was referred to as “cynanche trachealis and rattles;” in 1810 and 1811 it was also described as it appeared mixed with a typhoid epidemic.

The number of deaths from croup and diphtheria reported in New York from 1856 to 1877, were as follows:

Year.	Deaths from Croup.	Deaths from Diphtheria.
1856	550	None.
1857	560	2
1858	478	5
1859	622	53
1860	599	422
1861	460	453
1862	685	504
1863	908	981
1864	754	734
1865	449	589
1866	257	334
1867	76	38
1868	342	277
1869	255	158
1870	421	308
1871	457	238
1872	675	446
1873	732	1,151
1874	594	1,665
1875	758	2,311
1876	527	1,750

In 1814, at Aquia Creek, Va., there appeared an exceedingly severe distemper, which carried off entire families, and which was described as a violent sore-throat, attended with obstruction of the air through the windpipe.

The first case reported in the city of New York was by Dr. Willard Parker, at the New York Pathological Society, June 11, 1845. The specimen was accompanied by the remark that "the disease had prevailed extensively in the city."

On the 28th of January, 1846, Dr. John C. Peters presented before the same Society a specimen of "diphtheritic croup." Drs. Markoe and Sabine also reported cases within those years. From that time, 1846, the disease was comparatively lost sight of, until a case was reported by Dr. A. Jacobi.

In the City Inspector's report for 1860, death had been attributed to diphtheria in 422 cases; but it was said that no case had been recorded at the office prior to 1857. It was also stated by the City Inspector that, in his opinion, it was not contagious, and was curable in a large majority of cases.

The first mention of pseudo-membranous croup was of comparatively recent date, being made by Dr. Blair, of England, July 6, 1713, under the name "croops," which he described to be "a snorting at the nose, and a squeaking at the throat."

In 1755, Dr. Russell, of London, gave the distinguishing features between diphtheria and true membranous croup. Dr. Peters made further reference to the literature of croup and diphtheria, and the discussion was continued by

DR. JOEL FOSTER, who regarded membranous croup and diphtheria as two distinct diseases.

DR. ELISHA HARRIS regarded diphtheria as a self-propagating disease, and that when its infectious attribute had become fixed in any locality it showed a tendency to persist, especially in the midst of ordinary civic conditions. It could not be expected, therefore, that diphtheria, although upon the decrease, would entirely disappear, even in the present year.

DR. RODOLPH TAUSZKY took the ground that the two diseases were essentially distinct, and that their duality could be easily demonstrated microscopically, macroscopically, and clinically.

The following characteristics of the membranous deposit in the two diseases were given, accompanied by drawings of the histological appearances:

The exudation in membranous croup consisted of fibrillae, horizontally arranged and nearly parallel with each other, with slight interstices, which contain epithelia, mucous corpuscles with nuclei, mucous threads, a number of indifferent elements, and a few fat globules. The membranes examined were removed from the epithelial layers of the mucous membranes of the air-passages of children suffering from croup; the membrane could be removed easily and without doing the least violence to the tissues beneath. The fibrillae were the result of coagulated albuminates and changed epithelial formations.

The membranous exudation in diphtheria showed a distinct homogeneous framework, circularly arranged, forming nests filled with numberless joint and a few rod-like organisms, having all the characteristics of the so-called micrococci (not at all found in the exudation of croup), and which could not be made to disappear by the addition of glycerine, acetic acid, or sulphuric ether. The circular network was interwoven and infiltrated into the substance of the submucous connective tissue, from which it could not be detached without violence, and if removed left behind a bleeding surface.

The exudation of croup was colorless and of the consistence of fibrin, and could be partially dissolved by the aid of warmth, or the addition of acetic or hydrochloric acid. The structure of the exudation in diphtheria was looser, more easily separable after

removal from the body, and, like a substance containing albuminous matter undergoing decomposition, was turbid.

Dr. Tauszky maintained that in diphtheria micrococci might be found in all the organs of the body, having first entered from the atmosphere the local putrefactive process in the throat, and from there gained entrance to the system by means of the lymphatics. In that manner an additional poisonous element was added, hence the necessity for local disinfectant treatment, the object being to arrest the process of putrefaction, and destroy the animal organism. Dr. Tauszky gave an interesting account of the difference between catarrhal, croupous, purulent, and the putrescent or diphtheritic inflammation, and closed his remarks with a brief reference to the clinical features by which the two diseases were to be distinguished.

DR. GEORGE BAYLES remarked that the distinctive differences between membranous diphtheria and croupous laryngitis could be demonstrated better by every other symptom and condition than by such as were confined to the mucous surfaces of the respiratory passages.

It was in the localized symptoms that no certain distinction could be formulated to the satisfaction of all pathological observers; that is, *localized* as far as concerns the naso-pharyngeal and tracheal surfaces.

There was a localization in another sense, however, that would help to determine the real and radical differences existing between the two forms of disease, namely, *induced localization* of membranous deposits upon surfaces remote from those specifically affected, or destined to be affected. Upon surfaces artificially prepared to exude *liquor sanguinis*, diphtheritic pseudo-membrane might be looked for in cases of diphtheria, and naught but pure reparative coagulable lymph in cases of membranous croup, even when the laryngeal membrane of croup was at its worst in point of occlusion or mechanical obstruction of the respiratory passages.

To assume that croup had phases of character and degrees of intensity that altered its manifestations in so remarkable a manner without destroying identity, was simply to assume that croup or diphtheria, by whichever name it might be called, did not obey fixed laws of invasion, or of development; neither was it governed by any of the usual influences which obtained under certain and variable conditions, as of age, sex, locality, constitutional tendencies, infection, etc.

If common croup (that fleet evidence of nursery mismanagement) could become assimilated or pathologically associated with diphtheria, it would be because a "cold" had assailed a vitiated and depraved constitution, and had become the exciting cause of a croupous variety of diphtheria, the diphtheritic element being determined by the constitutional conditions previously prevailing. That would seem to be possible when we reflected that we could demonstrate the presence of diphtheria in the system even in the absence of the usual *throat* lesions, and even when from considerate treatment, or other reasons, the throat lesions failed to appear.

If, therefore, we were able to have croup without appreciable constitutional taint, either before or after the attack, and were able to have diphtheria without the laryngeal and faucial false membrane, and further, which would be admitted, if we were *not* able to have croup without the pseudo-membrane of the throat, and *not* able to have diphtheria without a constitutional involvement to some extent, however slight, why was it necessary, under any accepted system of patho-

logical reasoning, to regard the two forms of disease as essentially and generically one?

To amalgamate the two diseases would be to multiply the pathological and histological difficulties in the case to an inordinate degree, while to award croup and diphtheria a reasonable and separate identity, and study them accordingly, would doubtless be the right step towards acquiring a better knowledge of their real and independent natures.

Dr. BILLINGTON continued the discussion by replying to certain propositions submitted at the last meeting of the Academy, by Dr. J. Lewis Smith, in favor of the view that diphtheria was a specific primarily constitutional disease.

I. The first proposition was that diphtheria resembled such constitutional diseases in having a "long incubative period in certain instances. A week might elapse after exposure before symptoms of diphtheria commenced."

Dr. Billington, in reply, remarked that although the interval between exposure and attack in diphtheria varied from a day or two to longer periods, the same was true of other diseases not recognized as primarily constitutional. It was true of gonorrhœa; but that affection was not therefore a primarily constitutional disease.

II. "Severe constitutional symptoms, lasting for a longer or a shorter period—perhaps for twelve hours—might be present before the appearance of the usual inflammation."

Out of several hundred cases of diphtheria observed by Dr. Billington, he had never seen one so early that some indications of local inflammation had not been evident. Diphtheria, however, as was well known, often appeared in the course of other diseases, both general and local—a fact not in accordance with the usual behavior of specific, primarily constitutional diseases.

The presence\* of diphtheria was so appalling that there was liability to fail in bringing to its observation that cool analysis of symptoms which was given to less formidable diseases. Dr. Billington believed that when a thorough analysis was brought to bear upon the disease the conclusion must be confirmed that there was no symptom nor set of symptoms peculiar to the onset of diphtheria. The invasion of simple catarrhal sore throat was often attended—sometimes apparently preceded—by rigors, fever, anorexia, nausea, headache, general pains, etc. Many cases of non-diphtheritic throat-affection were attended from the first by marked constitutional depression. Those who had seen much of diphtheria must have met with grave cases of the disease, in an advanced stage of local manifestation, in which the general symptoms were so slight that no serious illness had been suspected.

III. "Early and repeated local treatment of the inflammation did not prevent the occurrence of symptoms of blood-poisoning in all cases of severe type. Local treatment was to be used to prevent septic poisoning, but it did not prevent diphtheritic systemic poisoning."

Dr. Billington replied that there was no known treatment that would at once subdue the inflammation, even in simple sore throat. In diphtheria some days generally elapsed before the exudation could be finally removed. Opportunity was, therefore, always afforded for the absorption of poison. No known treatment that was safe and practicable could be absolutely disinfecting, even in favorable cases—only approximately so. Toxic absorption from the affected surface, in greater or less amount, was therefore inevi-

table in every case of diphtheria. It was therefore regarded as illogical to consider some of the morbid phenomena of diphtheria as due to this assumed primary systemic poison, and the sepsis only to local absorption.

It had been claimed by some that the sequel, paralysis, because it followed mild cases as well as severe ones, must be due to primary systemic poisoning. On that point Dr. Billington remarked, first, that the conclusion was in no way warranted by the premises; and second, that the features of that paralysis—beginning as it usually did in the velum palati, and being frequently accompanied by evidences of tissue degeneration at that point of commencement, according to recent observations—were at least as suggestive of a local as of a constitutional cause.

Because water often failed to extinguish fire, it did not follow either that it was a valueless agent for extinguishing fire, or that the most destructive conflagration had other than a local origin.

IV. "The state of the kidneys afforded evidence of a constitutional malady. In certain cases of diphtheria the urine was albuminous as soon as any of it could be obtained. This was regarded as a strong point in favor of diphtheria being primarily a constitutional disease, whether the local manifestation was a pharyngitis or a laryngitis, for the poison penetrates the system before it reaches the kidneys."

Albuminuria in severe cases of diphtheria, and in many mild ones, was a familiar fact. The question, however, remained, was that phenomenon the result of a primary systemic or of the locally absorbed poison? If the result of the former, it should exist at that stage of the disease which preceded the occurrence of exudation. It might be said that such was the fact in certain cases. Dr. Billington replied that such instances were the exceptions to the general rule. He believed that albuminuria probably existed in the pre-exudative stage of diphtheria in no larger proportion of cases than of simple catarrhal affections of the same degree of severity, and from the same causes. In confirmation of his own observations upon that point, quotation was made from Dr. Robert Bell, of Glasgow, in the *British Medical Journal* of January 29, 1876, as follows: "The presence of albumen in the urine must not be looked upon as a necessary symptom of diphtheria; as it often does not manifest itself until far on in the disease; and, on the other hand, I have often observed albumen as a concomitant of ordinary sore throat."

Dr. Billington said, "I believe that the true interpretation of all the clinical and pathological facts of this disease is that upon the basis of a catarrhal inflammation is developed locally, by some influence—whether tendency from within or irritation from without, whether organic or chemical, no one at present knows—the morbid process which results in the diphtheritic exudation; that from this *foens et origo malarum* are absorbed the specific and septic poisons or poison of the disease, diphtheria; and that to this absorption is due everything that is distinctive in its constitutional phenomena."

It was believed that by accurately separating the constitutional symptoms peculiar to diphtheria from those which were not so, we should find in nearly every case that the time, order, and manner of their appearance were precisely such as to confirm the truth of the above theory. The few exceptional cases of marked disproportion between the constitutional symptoms and the local affection might be readily explained by the fact that diphtheritic exudation might and often did occur in localities where it was not visible; or by another familiar fact, not peculiar to diphtheria, that

in certain constitutional conditions there might be grave toxæmia by absorption from a trivial source.

OBSTETRIC SECTION.

Stated meeting, February 19, 1877.

DR. A. C. POST, CHAIRMAN, PRO TEM.

BELLADONNA AS A PRESERVATIVE AGAINST SCARLET FEVER.

DR. J. C. PETERS reported three cases of scarlet fever occurring in one family, recovery taking place in each. To the fourth child in the same family belladonna was administered for the purpose of protecting him from the disease, but it was contracted notwithstanding, and was the only case in the family in which it proved fatal.

Dr. Peters remarked that his experience in the use of belladonna as a preservative against scarlet fever had been large and unfavorable. In looking up the literature of the subject, he had found that Halmemann recommended  $\frac{1}{2}$  grain of a grain of belladonna, stirred in a glass of beer or milk, as a preservative against the scarlet fever of Sydenham, which Sydenham himself declared would get well of itself, if not disturbed by the officiousness of meddling doctors. Against the scarlatina maligna, however, Halmemann did not claim it to be preservative, but on the contrary regarded him as foolish who should so regard it.

OBSTINATE VOMITING—OXALATE OF CERIUM.

DR. PETERS reported four cases of obstinate vomiting, associated with different forms of disease, all of which had been benefited in a very striking manner by the use of large doses of oxalate of cerium after an almost endless variety of measures had been unsuccessfully employed.

The first case was one of cancer of the stomach. Oxalate of cerium was administered in doses of four grains every two hours, while the patient was awake, and continued until probably six hundred grains were taken within three weeks, not only without inconvenience, but with such marked benefit that food was taken and retained with comparative comfort.

In the second case the vomiting was associated with vaginismus. The third and fourth were cases of chronic dyspepsia. In the third the patient had been taking large doses of McMunn's elixir of opium and whiskey, but by the use of large doses of oxalate of cerium the vomiting was subdued, and both opium and whiskey were abandoned. The toleration of the drug was somewhat surprising.

VARICOSE VEINS—HEMORRHAGE ARRESTED BY HOT WATER.

DR. S. CARO was called to attend a woman in labor, who was the mother of twelve children and had had three miscarriages. She had never had any trouble in either labor or miscarriage. The doctor was called in haste on account of a sudden loss of a large quantity of blood from the vagina. Upon arrival he found that the fatal heart was still beating, the labor advanced to the second stage, and the pulse of the woman very feeble. The vertex presented, and in the first position. The doctor was not able to satisfy himself with regard to the source of the hemorrhage until by inspection blood was seen oozing quite freely from a ruptured varicose vein near the outlet of the vagina. A flannel compress was wrung from water as hot as could be borne, and the labiæ being separated, applied immediately in contact with the bleeding spot. The hemorrhage at once ceased. The pains being inefficient, and the uterus failing to respond to

the use of stimulants, the child was delivered by forceps, and was alive. After delivery there was a tendency to return of the hemorrhage, but it was easily and completely controlled by the hot water.

Whether the arrest of the hemorrhage was spontaneous, or was produced by the hot water, or by the compress, the doctor was not able to say positively, but it was to be remarked that the flow of blood quickly ceased after the application of compresses dipped in very hot water, both before and after delivery.

Correspondence.

THE CLIMATE OF FLORIDA.

MR. EDITOR:—In an editorial in your February 16th number, on the climate of Nassau, you take occasion to institute a comparison with that of Florida, to the discredit of the latter, basing your remarks probably on hearsay rather than on personal observation. As the subject of the comparative value of climates, especially of those most accessible to our people, is a very important one, and, as you say, growing in importance, and as *facts* are what you, and the writer, and the profession are anxious to gather, will you allow him to offer you a contribution, small though it be, of actual fact, as bearing on one of the statements contained in the editorial referred to, viz.: That "other influences characterize *particularly* (italics not yours) the resorts in Florida, which detract from their character as winter residences. Cold north-easterly winds laden with moisture, and even frost, may surprise the Northern sojourner in most parts of Florida during any of the winter months, and unpleasantly remind one of the lack of home comforts and protection against bad weather"? The impression conveyed in this sentence to the minds of those not conversant with the Florida climate is that a stay here in the winter would be rendered uncomfortable by cold winds, and particularly by north-east winds. Now, the *prevailing* winds of Florida in winter are not N.E. In most winters they are very exceptional. When they do prevail, they are not *cold* winds, nor disagreeable winds, except at some points on the *coast*. Along this river, where people from the North "most do congregate," they are generally pleasant, bracing winds, not necessarily unpleasant even when it is cloudy and rainy. They do not usually bring rain, the rainy winds in winter being the S.E. and S.W. It so happens this winter, however, that a most remarkable succession of N.E. winds *has* prevailed. So we may learn what they have brought us, at this point, from the following table, which presents the average temperature for each day, from thermometrical notes, taken carefully by the writer, at morning, noon, and evening:

Jan. 23.....	68	Feb. 4.....	69½
" 24.....	52	" 5.....	67
" 25.....	55	" 6.....	56½
" 26.....	62	" 7.....	59½
" 27.....	60	" 8.....	61
" 28.....	51½	" 9.....	51½
" 29.....	58	" 10.....	52
" 30.....	58½	" 11.....	55½
" 31.....	57½	" 12.....	60
Feb. 1.....	62½	" 13.....	61
" 2.....	62	" 14.....	57½
" 3.....	63½		

It rained, during these *twenty-three* days, on the morning of the 23d, that of the 7th, and that of the 14th; no whole day. Besides these rainy days, it was cloudy during the whole of the 4th and 6th of February, and during a part of the 26th of January, and of the 5th and 13th of February.

The lowest of the temperatures given in the above table were considered "bracing" and "pleasant" by both invalids and tourists here. In the morning and evening it was pleasant to be around the fire-places when in-doors, but at the same time an overcoat was generally not needed, except by invalids, out-of-doors. This is mentioned to show that, even at those comparatively low temperatures, the dampness was not felt to be an inconvenience.

Nassau has its advantages, but the uniform high temperature, especially as it is combined with a comparatively high degree of moisture, is not generally considered as one of them by those who have tried a prolonged residence there in winter. Nothing here is more likely to produce discontent and desire for change than a series of days characterized by a uniform high temperature, although the nights are always cool enough; and the cool changes, which are not infrequent here, are always hailed with satisfaction, and especially by those most seriously afflicted by pulmonary disease. This the writer has always considered one of the advantages of a Florida winter, and would recommend it in preference to one where "even moderate fluctuations of the temperature are rare, and frost is never known." Nor is there any lack of "protection against bad weather," as open fire-places or wood-stoves are sufficiently abundant everywhere, even in the humblest private houses.

The writer did not intend to trespass so far on your valuable space, but no climate has been more misrepresented than this. By some it is lauded as only second to heaven, by others abused as only a little more tolerable than that of a very opposite locality.

Respectfully yours,

F. D. LENTE, M.D.

PILATEA, Feb. 14th.

## LIFE INSURANCE AND THE MEDICAL PROFESSION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In your remarks of January 27th, upon "Frauds in Life Insurance," you clearly point out the practical weakness of the present system, in the lack of independence and authority in the medical managers. But permit me to say that, in my view, the cause and the remedy for this evil need a more careful examination.

Why is it that the medical examiner is not recognized by the companies and the public as the chief guardian of the business, the most responsible of all its officers for its success or failure? It is largely because of our defective legislation. If life insurance were conducted without special supervision by the government, and were left to the control of the laws of commerce and society, with such judicial supervision as applies to all other financial trusts, the companies would compete before the public upon the actual results obtained by their management; and the first element of success would necessarily be the scientific selection of risks by skilled examiners. Instead of this, the State has undertaken to superintend the business in its minutest details, and, by a system of examinations and reserves founded on a mathematical theory which

is but very remotely connected with commercial facts, it diverts public attention from these facts, and concentrates it wholly on these theoretic fictions. The certificate of the State is given alike to the strongest and weakest companies, to the great mutual societies of New York or Hartford on one hand, and to a Continental or a New Jersey mutual on the other; and puts them all on a dead level, so far as the healthy business competition, which appeals to the intelligence of the community, is concerned.

To be specific: this supervision, according to the law of this and every other State, expressly assumes that all the risks insured in all the companies are precisely of the same value; of that value, namely, which the legalized table of mortality represents, one company may have, in some cases does have, a rate of mortality three times as great as another; and the latter may then be perfectly solvent, in a sound commercial view, though it holds a reserve far below the State standard, while the former is commercially bankrupt, though its invested funds exceed the highest requirements of the law. State supervision, however, cannot legally take any notice of this fact; it must mercilessly destroy the solvent company, and hold up the hollow swindle as worthy of public confidence until the crash comes.

This law makes it an absolute necessity, first of all, for each company to make its apparent reserve good against the State day of reckoning. If, in order to do this, it is necessary to take business at random, to scatter its risks through dram shops and felons' dens, to insure the sick and dying, the necessity is on it, and it cannot hesitate. What can the examining physician do? The eye of the law sees only the cash in hand; it is fixed searchingly on the receipts and investments; it is utterly blind to the selection of risks. He may protest, but there is no power to sustain his protest, and, as far as the State is concerned, he has neither influence nor responsibility. While such laws exist, the medical profession will always be thrown into the background in the management of the business; their position can never assume its proper importance. You are unquestionably correct in holding that the post of medical director is as potent for good or evil in a company as that of "Actuary, General Agent, or President;" but all these officers are under the immediate pressure of the law, recognized by it and compelled to meet its continuous requirements, while the law does not acknowledge the existence or work of the medical man. Of course, if his duties appear at any time to come in conflict with these requirements, they must be overruled.

If any State supervision of companies be proper, it is a State Medical Board to superintend the selection of examiners, and to hold them responsible to faithfulness in their work. But this is unnecessary. If the State would cease to belittle and obscure the medical side of the business—the very source of its vitality—by giving an unfair and exclusive prominence to a merely theoretic view of its financial aspects, we should soon see the companies forced, in self-preservation, and in their competition for good risks, to bring the medical guardianship of their safety into proper respect and control.

Yours respectfully,

SECRETARY.

CHARITY HOSPITAL, N. Y.—The following are the statistics of this hospital for the past year: Patients in hospital, January 1, 1876, 804. Admitted during 1876, 7,817. Cases treated during the year, 8,621.

ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from February 18th to 24th, 1877.*

COOPER, GEO. E., Asst. Medical Purveyor. Relieved from duty in Dept. of California, and to relieve Surgeon R. Murray of the charge of the Medical Purveying Depot in San Francisco, Cal. S. O. 40, A. G. O., Feb. 21, 1877.

GARDNER, W. H., Asst. Surgeon. Assigned to duty at Greenville, S. C. S. O. 36, Dept. of the South, Feb. 17, 1877.

BUCHANAN, W. F., Asst. Surgeon. Assigned to duty at Morganton, N. C. S. O. 38, Dept. of the South, Feb. 20, 1877.

GARDNER, E. F., Asst. Surgeon. To report to Commanding General Dept. of Dakota for assignment to duty. S. O. 41, A. G. O., Feb. 23, 1877.

SHUFELDT, R. W., Asst. Surgeon. To report to Commanding General Dept. of the Platte for assignment to duty. S. O. 11, c. s., A. G. O.

PERLEY, H. O., Asst. Surgeon. To report to Commanding General of Dept. Dakota for duty. S. O. 41, c. s., A. G. O.

Medical Items and News.

CONTAGIOUS DISEASES.—Comparative statement of cases of Contagious Disease reported to the Sanitary Bureau, Health Department, for the two weeks ending February 22, 1877.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-Spinal Meningitis.	Measles.	Diphtheria.	Small-pox.
Feb. 17.....	0	7	67	3	2	42	0
Feb. 22.....	1	6	82	4	3	45	0

CHARITABLE BEQUESTS.—Miss Mary Dausser, of this city, lately deceased, made the following bequests to the charitable and medical institutions of this city: New York Eye and Ear Infirmary, \$5,000; Home for Incurables, \$20,000; New York Society for Prevention of Cruelty to Children, \$10,000; New York Juvenile Asylum, \$10,000; North-Eastern Dispensary, \$5,000; Sheltering Arms, \$10,000; Nursery and Child's Hospital, \$5,000; Northern Dispensary, \$5,000; Homœopathic Medical College, \$5,000; North-Western Dispensary, \$5,000; De Witt Dispensary, \$5,000; Homœopathic Dispensary, \$5,000; New York Society for Relief of Ruptured and Crippled, \$20,000; Eastern Dispensary, \$5,000.

UNIQUE ABDOMINAL LESION.—Dr. J. L. Coombs, of Grass Valley, Cal., writes: "In relation to the case of a child reported by Dr. John S. Coleman, of Augusta, Ga., in the number of your journal for Feb. 3d inst., 'occasional attacks of malarial fever from its birth' is mentioned as a condition existing before the injury. Not being able to suggest the actual 'neuro-pathological' condition, still it occurred to my mind at once that the use of arsenic in medicinal doses may have been a factor in the production of the consti-

tutional condition which existed at the time of injury."

UNIVERSITY MEDICAL COLLEGE, N. Y.—The Thirty-sixth Annual Commencement of the Medical Department of the University of the City of New York took place at the Academy of Music, Feb. 20th, in the presence of an unusually large and brilliant assemblage. The auditorium, orchestra, parquet, and balcony were crowded with friends of the institution, tully one-half of whom were ladies. On the stage, which was handsomely decorated with flowers, were seated the members of the Faculty and other distinguished guests. The music was furnished by Grafulla, and comprised selections from Strauss and other popular authors.

The Mott gold medal for the best anatomical preparation was conferred upon Mr. M. M. Johnson, of Connecticut, and the silver prize upon Mr. Alexander Dallas, of New York. Honorable mention for proficiency and superior excellence in this examination was made of the following gentlemen: H. C. Toal, F. A. Gillen, C. A. L. H. Von Ramdohr, M. T. Scott, A. G. Païne, Jay Owens, L. Haupt, G. L. Krieger, F. W. Brown, H. H. Coleman, W. P. Bowen, H. T. Dawson, S. Koen, A. E. Prince, and W. E. Cladek.

The address was delivered by Bishop Quintard. It contained a pleasant reference to the past thirty years' history of the institution and of the noted men who had been connected with it, and was full of sympathy and encouragement for the graduates before him. At the same time he cautioned them against over-confidence, and reminded them that perseverance and constant study were as necessary in the physician as in the student. Theirs was a burdensome profession, often an overtasked and unremunerative one, and patience and courage were, above all things, necessary. The Bishop did not side with those who thought a strictly medical education sufficient for a good physician. A liberal allowance of academical studies, especially Greek and Latin, were essential to a man of thorough cultivation, and certainly would not detract from a physician's usefulness or capacity for improvement. He would especially urge upon them a spirit of manly independence and self-reliance. The address was listened to with marked attention and elicited much applause. During the evening Chancellor Crosby conferred degrees upon one hundred and fifty-seven graduates.

ALUMNI ASSOCIATION OF UNIVERSITY MEDICAL COLLEGE.—The sixth reunion dinner of the alumni of the Medical Department of the University of the City of New York was held at Delmonico's, Friday, February 23, 1877.

A large number of alumni were present, and also the members of the graduating class, with some distinguished representatives of the other professions as invited guests. The dinner was, as usual, a sumptuously elegant one, and was enjoyed accordingly. Prof. Charles Inslee Pardee, the President of the Association, occupied the chair, and very gracefully performed the duties of host. The following were the regular toasts, with their respondents:

"The University of the City of New York," Rev. Howard Crosby, D.D. "Our sister colleges," Prof. T. Gaillard Thomas, M.D., and Prof. Fordyce Barker, M.D. "Our public charities," Hon. Isaac H. Bailey. "Our Alumni Association," James H. Anderson, M.D., class of 1860, President elect. "The clergy," Rev. Alexander R. Thomson. "The bar," Hon. Robert B. Roosevelt. "The press," Hon. Noah Brooks.

All of the speeches were well-timed and enthusiastically encored. Then followed impromptu remarks from several gentlemen called out by the President. Those of Dr. A. E. Macdonald, and the recitations of Mr. Andrews, were particularly well received. The Alumni Association prize of \$100 for the best thesis on consumption was awarded to Dr. Ghislandi Durant, of this city.

**BELLEVUE HOSPITAL MEDICAL COLLEGE.**—The exercises attending the Sixteenth Annual Commencement of the Bellevue Medical College Hospital, held at the Academy of Music, attracted a large audience. The stage was occupied by the Faculty of the college, and a large body of the representative physicians of the city. The seats immediately behind the orchestra were appropriated to the use of the graduating class, which numbered 147. After a prayer by Rev. Dr. Beach, the degrees were conferred by Dr. Isaac E. Taylor, President of the Faculty. The following prizes were then awarded: For the best clinic report, \$50, George Mingies; for the best examination in obstetrics, \$50 was equally divided between A. W. Rand and B. M. Disbrow; for best examination in physiology, \$50, George S. Conant; and for the best essay on psychology, \$50 was awarded to A. R. Robinson. In his address to the graduates, Dr. McCosh congratulated them on having chosen "about the highest of all professions." No one, he said, sees so much of human nature as the practising physician. He has less of routine than any other, having some new phase of character or disease to come under his care every day. He was glad to testify that physicians were generally tender-hearted, and he believed they gave more in charity and did more charitable work than any other class. He advocated very strongly raising the standard of medical education, and was astonished to hear that Bellevue College had no endowment fund. He knew that there was money in this country, and there were many generous men—as an evidence of which, he said, the college with which he was connected had received, in some mysterious way, within the past few years, \$2,500,000. After insisting on the need of an endowment and the addition of new branches of study, the speaker said the best way to prevent an over-crowding of the profession, of which there was some complaint, would be to require more thorough study. With some pleasant words of encouragement to the newly-made doctors, the address, which had received marked attention, was brought to a close. Elisha D. Lellingwell delivered the valedictory.

**A NEW BILL FOR A STATE BOARD OF HEALTH FOR NEW YORK.**—A bill has been introduced into the Assembly, the main provisions of which are as follows:

That the Governor appoint eight persons, one from each judicial district in the State, five of whom shall be physicians of not less than ten years' professional experience, who, with the Health Officer of the Port of New York, the President of the Board of Health of New York, and the President of the Board of Health of Brooklyn, shall constitute the State Board of Health. Of the eight persons first appointed, two shall serve for two years, two for four years, two for six years, and two for eight years.

That the State Board of Health shall meet at least once in every three months. No member of the Board shall receive any compensation excepting the Secretary; but the actual travelling and other expenses of the members while engaged in the duties of the Board shall be allowed and paid out of the appropriate

tion made for its support. They shall select, annually, one member of the Board to be President, and one of the medical members to be their permanent Secretary and executive officer, who shall keep a record of the acts and proceedings of the Board, and shall receive an annual salary of \$3,500. Then follows the usual detail of duties of the Board, regarding the care of public health, the making of sanitary surveys, the inspection of public institutions, registration of births, marriages and deaths, etc., etc.

**BOGUS DIPLOMAS.**—The following correspondence will explain itself:

[Copy.]

CAMP STAMBAUGH, WYOMING TERR., Feb. 7, 1877.  
*Surgeon-General U. S. Army, Washington, D. C.:*

SIR:—I have the honor to enclose herewith, for the information of the Surgeon-General U. S. A., a communication received by me on the 6th inst.

Very respectfully your obedient servant,

[Signed] CHARLES H. DODGE,  
*Hospital Steward U. S. A.*

[Copy.]

BUFFALO, N. Y., January, 1877.

SIR:—Do you want a medical diploma? Some hospital stewards have obtained diplomas through our agency, and are practising successfully. Many are well qualified, but lack diplomas. The agent, having been a hospital steward during the late war, knows whereof he writes. Fully one-fourth of the physicians in the United States have procured their diplomas through our influence.

Through the private agent of a medical college which cannot be questioned, you are proffered a diploma for the consideration of fifty (\$50 <sup>00/100</sup>) dollars. *No security is given, but the diploma will positively be forwarded by registered mail. Send money by registered, or ordinary letter, at the agent's risk. A limited number only will be disposed of. If you cannot invest, please hand this to one who may.*

An early reply is particularly requested.

Yours truly,

JOSEPH P. DONNER.

Address 580 Louisiana street, Buffalo, N. Y.

[We have received several copies of the above advertisement, forwarded to us by hospital stewards stationed in every section of the country. There is no doubt that the agent is making strenuous efforts to extend his business. Cannot some of our friends in Buffalo look after him?—ED.]

**HORSE-HAIR FOR THE DRAINAGE OF WOUNDS.**—

Among the modifications suggested in Lister treatment, but which is also applicable to other methods, is the substitution of horse-hair for the ordinary rubber drainage-tube, or the carbolyzed catgut drain of Mr. Chiene of Edinburgh. A coil of horse-hair, varying in strands according to the depth of the wound, is soaked for a considerable length of time in strong carbolic acid solution (1-20). This is then passed through the wound in the usual way, strands being taken out until the whole is removed. Catgut is regarded as superior to horse-hair, because it absorbs, while the capillarity of the latter is greater, and it is far cheaper. It is also far less irritating than rubber. —*Lancet*, Dec. 2, 1876.

**DR. GURDON BUCK.**—On going to press we learn, with the deepest regret, that the health of this distinguished surgeon, so long in a precarious state, is being so rapidly undermined as to give rise to the greatest anxiety.

## Original Lectures.

## ON THE PLANS FOR THE JOHNS HOPKINS HOSPITAL AT BALTIMORE.

A LECTURE GIVEN TO THE MEDICAL PROFESSION OF BALTIMORE, FEBRUARY 5, 1877.

By J. S. BILLINGS, M.D.,

SURGEON UNITED STATES ARMY.

## PART II.

We will now pass in rapid review the plans of a few existing hospitals, before showing the one proposed for the Hopkins Hospital.\*

The first is that of the great hospital at Milan, the Maggiore, which in the last century was considered a model, and which can contain over 3,000 patients. The principal wards form two crosses, one on either side of a central yard; they are over 30 feet high, with vaulted ceilings, brick floors, and windows, the sills of which are about 15 feet above the floor, being placed above corridors on either side.

There is no heating apparatus; small iron stoves were used at the time I was there, the pipe projecting from a window. One wing of the cross was unoccupied and was being cleansed and purified; this, I was told, is done in regular rotation in each wing. The air in the main wards was pure; in the other, or corridor wards, it was offensive. I saw nowhere a prettier sight than was presented by the children's ward in this hospital, and nowhere a sadder one than the ward for inevitably fatal cases, in which are collected cases of cancer, etc., and to be moved into which may be taken as a death warrant.

The next plan which I show you is that of the celebrated Lariboisière, at Paris, with which I have no doubt you are all familiar, as it was the first hospital methodically constructed on the pavilion plan. The ventilating apparatus for this hospital has not proved satisfactory, for the reason that the flues and openings are too small, and the power applied insufficient. The next is that of the new City Hospital at Berlin, the Friedrichshain, the plans of which were prepared in accordance with the advice of Dr. Esse and Professor Virchow, and which may be considered as the most recent attempt in Germany to obtain perfection in a hospital, regardless of expense. The plot of ground occupied is situated in the suburbs of the city, and measures about 900 by 1,200 feet, containing 23½ acres.

The buildings consist of six two-story pavilions, four of one story, and two for isolating purposes, with an administration building, a kitchen and laundry, a mortuary, a bath-house and a nurse's home, and these buildings are entirely isolated from each other, being scattered over the entire lot and having no connecting corridors, but merely uncovered asphalt walks. The distance from the kitchen to the farthest ward is about 900 feet; and the day I was there, which was a cold one with snow on the ground, I saw the female employees bare-headed and bare-armed, carrying the food to the wards under circumstances which would certainly cause great complaint in this country. I could not learn, however, that lung diseases or catarrhs were specially prevalent among those thus exposed. The pavilions are built of brick and are handsomely finished, with tiled floors in the surgical wards. No clinics

are held in this hospital, nor are students admitted. The total cost was 4,520,789 marks, or about \$1,200,000; equal in this country to about \$3,000 per bed.

The next plan is that of the Rudolph's Hospital in Vienna, which is the most recent large hospital in that city. This is on the corridor plan—the buildings being three stories high, and arranged around a central garden. The heating and ventilation are effected by large stoves of a peculiar kind, and the results are good, which is due largely to the careful superintendence of Professor Boehm, the manager of the hospital, who devised this method. Professor Boehm has made a special study of this subject of ventilation, and has arranged the apparatus for that purpose in the new Grand Opera-House at Vienna, which I had the pleasure of examining in his company. The arrangements are exceedingly complicated, more so than any I have ever seen, unless it be in the new Houses of Parliament in London. The system is one of combined impulsion by a fan and aspiration by means of gas jets, and the result is success, which, however, could only occur with skilled and careful management.

The next plan is that of the Jacobs, or City Hospital, in Leipzig. Here the pavilions are all one story, with ridge ventilation, connected by a corridor, and heated by large German porcelain stoves in the wards. It is difficult to obtain sufficient warmth in very cold days in winter, and in still warm days in summer there is very little movement of air.

The next plan is that of the new hospital at Wiesbaden, in which the pavilions are placed in echelon on the sides of a triangular plot of ground with the Administration building at the apex.

With the plans of the principal English hospitals, such as St. Thomas and the Herbert, I presume that you are sufficiently familiar. I regret that the plan of the new Royal Infirmary at Edinburgh has not yet come to hand. This hospital is now in process of construction, and will, when completed, be one of the first buildings of this kind in Great Britain, if the heating arrangements prove sufficient. It consists of two rows of two-story pavilions, connected by an H-shaped corridor somewhat on the plan of the old Satterlee Hospital in West Philadelphia. We will now look at the arrangements of the ward in one or two of these hospitals.

The first is of one of the Leipzig hospital wards. In this there is a large sun or day room at the farthest end of the ward, and the service-rooms are next the corridor, in fact, actually in the ward itself; yet there is no unpleasant smell, owing to the regular and frequent use of disinfectants.

The next is the plan of one of the one-story surgical wards of the Friedrichshain Hospital. The heating is by hot water; the warm fresh air is brought in the middle of the ward to the top of a sort of table covered with wire netting, and is taken out through registers placed at the side near the floor, being drawn downwards into a duct which passes into an aspirating chimney. This chimney is driven in part by the waste heat from the furnace which effects the heating, and in part by a separate furnace intended exclusively for this purpose. The arrangements of valves and ducts is a complicated one, and should have skilled supervision to produce the best results. The consumption of coal for each pavilion is about 1800 pounds per day. In this as in all European hospitals the patients dine in the ward, but a day-room is provided for those who are able to leave their beds, and this is separated from the ward by the large chimney which rises in the centre.

\* The plans referred to were shown on a screen by means of a magic lantern.

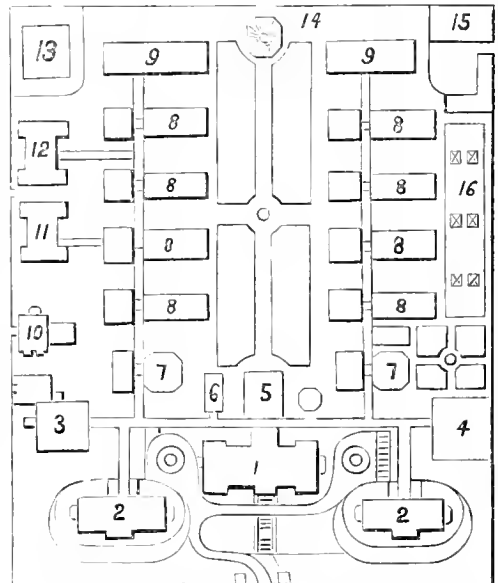

The next plan is that of two floors of the new pavilion recently erected in Chicago for the Cook County Hospital. This pavilion is four stories high, three of which are occupied by wards. It is heated by steam, and ventilated by a large aspirating shaft which passes up the centre of each ward. The heating has not proved satisfactory during the very cold days of the past winter, but it is said that this is due rather to bad management than to defect in the apparatus. The air in the lower wards is purer than in those above. The closet and bath rooms are, as usual, at the end of the ward remote from the connecting corridor, but are placed at one side, around a separate shaft which has independent aspirating power. On the other side is a small ward for isolating purposes, heated and ventilated mainly by a fire-place. This arrangement is taken from the plan which I first proposed for the Hopkins Hospital, and has some special advantages, particularly as regards the isolation of the patients in the small wards. The next plan is that of one of the wards of the Roosevelt Hospital in New York city, in which, by a peculiar arrangement, the service rooms at the remote end of the wards are so placed that they form no projection beyond the side of the ward itself.

The next plan is that of a floor of the new building now in course of construction by the authorities of the New York Hospital. This building is seven stories in height, will accommodate two hundred patients if crowded, and will cost about \$750,000. All the floors are tiled, and the only wood-work in the building is in the window-sash, doors, and door-frames. The heating is effected by steam, the ventilation by a fan for impulsion placed in the basement, and another fan for aspiration placed in the top of the centre building. The experiment is a bold one, and the results obtained, if carefully observed and accurately reported, cannot fail to be of interest.

The next plans are those of wards proposed for the Johns Hopkins Hospital. It has been considered by the building committee very desirable that the south end of all the wards should be entirely clear of service rooms, and be freely exposed for light and air, and these plans are arranged to carry out this idea. The one which is most generally preferred is that in which the ward is entirely separated from all service rooms, these last being collected in a building placed in the opposite side of the corridor. The majority of those whom I consulted, expressed doubts as to the advisability of removing all the service rooms to the north end of the ward, but admitted that if thorough ventilation and cleanliness could be preserved, the objections to it were rather theoretical than practical. A few critics insist that the nurse should have a separate room connected with the ward. This applies especially to the male wards in connection with the employment of female nurses, and is urged by some of those who are especially interested in this department. As I understand the duties of the female nurse, they are to be performed in the ward itself. I consider that to be her room, the absence of which is complained of, and while on duty, her place for rest is in the middle of it.

I now show you the block plan proposed for the hospital. The lot upon which it is to be placed has an area of about fourteen acres, and is situated on the side of a hill within the limits of the city. The buildings proposed consist of an administration building, and two wards for pay patients on the west, or main front, looking down towards the city; two octagonal wards of two stories each, eight one-story pavilion wards, two isolating wards, some tents; the nurses' home, the kitchen, the dispensary and operating

theatre, a mortuary building, an apothecaries' establishment, a bath-house, a laundry, a residence for the superintendent, a green-house and stables. The wards are arranged around a central garden, with the south ends projecting free. The operating theatre, dispensary, and mortuary building, are placed near the adjacent square upon which the medical school is to be situated. The wards, administration building, and kitchen, are connected by a corridor of the same height as that of the basements of the wards, namely, ten feet, so that the top of the corridor forms an open terrace walk, level with the floor of the wards.

BLOCK PLAN FOR PROPOSED JOHNS HOPKINS HOSPITAL.

EXPLANATION.—1, Administration Building; 2, Pay-Wards; 3, Kitchen; 4, Nurses' Home; 5, Dining-rooms for Medical Officers and Nurses; 6, Pharmacy; 7, Two-story wards; 8, One-story wards; 9, Isolating wards; 10, Residence of Superintendent; 11, Dispensary; 12, Operating Theatre; 13, Mortuary Building; 14, Green House; 15, Laundry; 16, Space for tents.

This plan is approved by the majority of experts to whom it has been submitted; but as you may easily infer from the widely different plans of some of the most recent hospitals both of this country and of Europe, which I have shown you, it cannot be said that the general principles of hospital construction are as yet settled on any scientific basis of observed facts, and I found, in fact, nearly as many opinions as persons,—opinions often marked by all that decision and breadth of statement which distinguish those of persons unbewildered by the slightest experience." I met with distinguished medical men and professors who object to the pavilion plan, who prefer wards with corridors at one side to those with opposite windows, who thought that there might be too much ventilation for a sick man, setting aside the question of draughts, and who spoke of a stuffy atmosphere as a good thing for certain cases. Some wished to concentrate the buildings as much as possible, but the majority prefer, when it can be done, to scatter and isolate them.

I have not time to show the plans of the general buildings, but I will call your attention to one, namely that for the dispensary and the operating theatre.

I consider this dispensary for the treatment of the sick poor who remain at their own homes, as one of the most important features of this hospital, both of

account of the amount of suffering which may be relieved by it, and on account of the means of instruction for nurses and students which it affords. I therefore inquired particularly into the working of similar institutions abroad, and especially into that of the largest one, at St. Bartholomew's in London, where between 600 and 1,000 patients are seen and prescribed for daily. The plan before you is for two one-story buildings connected by a corridor. It is mainly through these and the mortuary building that I think the medical school should be connected with the hospital, and the general arrangements appear to me to be satisfactory for that purpose.

The responsibility of recommending one particular plan for this hospital, to the exclusion of all others, is very great. The whole subject of hospital construction is at present in a revolutionary condition. With almost every existing hospital there is more or less dissatisfaction, while from the most recent attempts to produce a perfect structure, the results are not yet known. I cannot learn how much healthier one-story wards are than those of two stories or more; the general opinion is, that they are better and more easily ventilated, that is all. It is objected by some that the buildings are spread over too much ground, and that it will be difficult to administer it, but the Friedrichshain is still more scattered, and has greater distances, and yet seems to work very well.

In organizing the university, or the medical school, it is possible to proceed gradually and tentatively, getting the most important thing, namely the men, first, and leaving the buildings to be a gradual outgrowth of the necessities; but if anything like a permanent structure is proposed for the hospital, the plan of the buildings must, to a great extent at least, be first decided on, and this is peculiarly the case in the plan proposed, where it will be desirable that the foundations of all the buildings on the west front be laid before grading is commenced, in order to avoid excavations in newly deposited earth, which buildings are the largest and most costly of the establishment.

In recommending to the trustees that this general plan be adopted, I have been influenced by the following considerations:

1. Will the sick in the wards be placed in the best possible conditions as to light, pure air, warmth, etc., so that there shall be nothing in the surroundings to hinder their recovery? The answer to this is yes, and it may be considered as unanimous, for the advocates of other plans do not claim that their plans are better as regards the sick, but that they are as good.

2. So far as the medical department of the university is concerned, and as giving the necessary facilities for the education of physicians, and for advancing our knowledge of disease, are these plans satisfactory? The answer is yes, and is, I believe, unanimous.

3. So far as the training of nurses is concerned, are these plans suited to induce the class of women whom it is desired to secure—to enter and remain in this hospital? To this also, the answer is in the main affirmative, although doubts are expressed by some.

4. Are the plans practicable, and to be approved from the point of view of the architect and engineer? The answer is yes.

5. Can as good results be obtained by some other plan which shall cost much less in construction, or in administration, or in both; or if the results may perhaps be not quite so good, cannot relief be afforded to a greater number of people with the same expenditure? In other words, taking all things together, cannot the money be better employed in building a cheaper hospital, which shall also be more compact and

cheaper to manage, and which if not certainly as good in the hygienic, educational, or architectural point of view, will yet afford a sufficiently good care to a larger number of persons.

Upon this question there are great differences of opinion. Some hold that the expenditure upon the buildings of an hospital should never exceed \$1,000 per bed, and that the cost of administering it should never exceed \$1.00 per day, per patient, while others say that the best possible results should be aimed at regardless of the cost.

As I have above stated, I feel warranted in saying to the trustees that the plan submitted is, from the point of view of the physician, the hygienist, the architect, the educator, and the investigator, in all respects as good as, and in some better than, that of any hospital now in existence, or which has been proposed.

I must also say that, constructed as the architect proposes to construct it, it will be a solid and substantial group of buildings, and a comparatively costly one.

It will also be more expensive to manage than the great majority of hospitals of its size in existence, but it will accomplish more.

If I supposed that the number of sick poor in the city of Baltimore in urgent need of the aid of this charity was in excess of the number who can be provided for in this plan, I should advise such an amount of change and consolidation as would admit of doing the greatest good to the greatest number.

As I have no reason to think this, or that even 300 beds would not at the present time be sufficient to meet the demands upon this charity, I advise the adoption of the plan presented, but I recognize fully that this is not a medical, architectural, or scientific question, but one of finance, which belongs peculiarly to the trustees to determine, and their decision of which, whatever it may be, will be unsatisfactory to a certain number of persons. The question of cost in this case means, first, the time when the hospital shall be open to patients; second, the number to be cared for.

I base my recommendation upon the belief, that *in this particular case* it is best for the sake of the sick, of the school, and of suffering humanity throughout the world, to try to give to what patients we do receive, the very best possible facilities for treatment which modern science can suggest, and that the result cannot fail to be a valuable one.

I do not, and cannot say that the plan I have recommended is the best possible plan; but I believe it complies with the direction of the founder, that "it shall provide for an hospital which shall, in construction and arrangement, compare favorably with any other institution of like character in this country or in Europe."

Certainly I have seen nothing which I think superior, or in some respects equal to it; and if it has a medical, surgical, and nursing staff, and a superintendence of corresponding quality, I am quite sure that the results of treatment obtained in it will not be surpassed elsewhere.

In conclusion, permit me to express the hope that the physicians of Baltimore will not fail to take that interest in the plans for, and progress of, this hospital which is certainly due to the splendid possibilities which it presents for the promotion of the science and art of medicine.

Over in Washington, only an hour's ride away, there is open to all physicians a collection of medical literature unsurpassed in extent, variety, and value for practical work; while very soon in your own city you will have laboratories and hospital buildings as com-

pletely fitted for purposes of research and the promotion of increase of knowledge as any in the world.

But the books and buildings, machinery and apparatus thus provided, will not do the work. Remember the question asked by Professor Huxley, "What are you going to do with all these things?" Where shall we find the men who will make the best use of these opportunities; men who will not only teach the few students who may gather here, but all studious thinking medical men in all countries, because they will make known new signs, means of prevention, and methods of treatment of disease? Men who can impart to their pupils not only knowledge, but a thirst for knowledge, thus preparing worthy successors to themselves, and who will make the name of this city as well known in medical literature as were the names of Cos and Silerum of old.

These are problems the right solution of which is as important to the hospital as to the university. I commend them specially to your attention, and I hope and believe that at last satisfactory practical answers will be given; in which case there can be no doubt that in the fulness of time those results will be obtained which, both as physicians and as citizens, I am sure we all desire.

## Original Communications.

### NEEDLE IN LARYNX—REMOVAL BY EXTERNAL INCISION—RECOVERY.

By CHAUNCEY MITCHELL FIELD, A.M., M.D.,

OF BOUND BROOK, N. J.

PATIENT, Miss M. E. B. of Bloomington, N. J.; age twenty-five years; fine physical development. While dressing to attend an evening concert, and attempting to fasten a rosette on the bosom, the thread broke. Carelessly placing the needle between the lips she sought another thread, and while so engaged, on drawing a long breath, it slipped from its embrace, and lodged itself in the larynx.

The patient was immediately seized with violent coughing and choking, and in her extreme distress and suffering she rushed (seeking air) to the door and out of the house. In a short time the attack ceased, and she breathed freely for a few minutes, when again suddenly intense dyspnea, with coughing and strangling, came on, the face becoming tumid and purple, and the patient nearly suffocated.

At 8 p.m. I saw the patient, within half an hour after the unfortunate accident. On my arrival I found her sitting in an arm chair erect, holding the throat with her hands, greatly excited, breathing rapidly, not laboriously, and manifesting severe pain.

Quieting the nervous excitement by a few assuring words, the breathing became natural, simply marked by extremely cautious inspiration and expiration; continuous and repeated attempts at swallowing. When spoken to she answered plainly and distinctly, though she complained of pain at the time. There was no change whatever in the character of the voice.

On examining the throat I found a very slight prominence at the lower edge of the cricoid cartilage, and to the right (patient's) of median line, the patient placing her finger on the spot, and saying "she knew it was the needle," and complaining of pain on pressure of the spot.

I first tried the laryngoscope, but the excitability and irritability of the whole larynx made it useless.

On consultation with Dr. B. B. Matthews it was decided to attempt removal of the foreign body, or at least open the trachea. The patient having been anesthetized I made an incision three-quarters of an inch long in the median line over the cricoid cartilage. Coming down on the cartilage, and using this as a guide, I shoved the tissues aside with the handle of the scalpel until I arrived at the prominence indicating the *habitat* of the needle, the rays from a lamp furnishing certainly not the best light for such operation. Then, introducing finger and feeling the prominence, I determined to cut directly through it, hoping to come down exactly on the enemy. As I made the incision, steadying the trachea with the fingers of my left hand, the patient vomited, and then followed an attack of coughing and strangling until her face and neck were decidedly congested, and causing me to lose the locality of the trouble. This passed off in a very short space of time, and again finding the prominence I steadied the trachea with the left hand and incised the cartilage through its whole thickness; then passing a probe I hit the needle, and taking an ordinary dissecting forceps, after two abortive trials, on the third attempt I seized the needle by the head and succeeded in extracting it. Its position was across the larynx antero-posteriorly; head anterior, point sloping slightly upwards, backwards, and somewhat to the left of the median line, evidently piercing the posterior wall of the larynx. On its removal immediately every disagreeable symptom disappeared. The body is an ordinary sewing needle, size number seven, and was black as they are found when removed from other parts of the body. The hemorrhage was very slight. The edges of the incision were brought together by means of adhesive plaster and united by first intention.

Patient has never had any disagreeable symptoms since, and made an excellent recovery.

On consulting Gross on "Foreign Bodies in the Air-Passages," I find the records of three cases of some interest in this connection.

First—The case of De Ea Mertiniere,\* where a pin entered the trachea from outside through the integument. The patient (boy) had convulsions, and was breathing laboriously and scarcely living. On examining the trachea he felt, deep under the skin, *just below the cricoid cartilage*, a small circumscribed swelling the size of a lentil, and of unnatural hardness. Taking this as a guide he cut down as far as the trachea, where he came in contact with the foreign body projecting more than a line. After some difficulty he succeeded in extracting it with a pair of tweezers. The foreign body was a headless brass pin, fifteen lines in length, and had traversed the trachea from left to right and pierced its posterior wall.

The success of the operation was complete.

Next—A case by Mons. P. F. Blandin,† in which a man let a needle slip through the nose, together with a large thread, into the larynx. Much cough and irritation followed. Patient suffered remarkable hoarseness, dysphagia, and *almost entire aphonia*. (This may have been due to the swelling of parts, as record states that the larynx was much swollen, since in my case there was no change in the voice.) Laryngotomy was performed, the thyroid cartilage being divided in its whole length along the median line; still the needle was not extracted, but the next day was found in the dressings of the wound (19) nineteen lines in length, and of black color.

\* P. 51, Gross on Foreign Bodies.

† *Ibid.*, p. 297.

The cure was complete.

Again—J. Kearney Rodgers performed laryngotomy\* for a supposed needle in larynx, but none was discovered. The wound was closed, healed, and patient ultimately did well, though the foreign body was not known to have been removed.

Lustly—Mott† removed a shawl-pin from trachea of a small child; but this pin had a large glass head, which partially blocked up the passage, and so places case somewhat in another class.

## A CONTRIBUTION TO THE HISTORY OF HYPERMETROPIA.

By EDWARD T. ELY, M.D.,

NEW YORK.

It was not until Prof. Donders's publications in 1858-1859 that the importance of the ocular defect known as hypermetropia, together with its nature and treatment, were fully and correctly shown. It now occupies such a prominent place in ophthalmology, and its proper recognition and treatment have given such beneficent results, that everything connected with its history acquires a special interest. This leads me to call attention to an article which was published in this country nine years before Donders published his views. It was written by Prof. Chester Dewey, and appeared in *Silliman's Journal* (Vol. 8, p. 443) in 1849. I was led to look over the files of the journal by my father, Dr. W. W. Ely, of Rochester, N. Y., who told me that Prof. Dewey had often talked with him about a peculiar form of vision which he had noticed, and that he had at one time given a written account of it. The article is quoted just as it appeared. In a subsequent number of the journal, the author calls attention to the matter again, and reports some additional cases:

"On an Unnoticed Kind of Abnormal Vision.

"BY PROF. C. DEWEY.

"There are two well-known kinds of *abnormal vision* in eyes not diseased, the *far-sighted* and the *near-sighted*. The former occurs in good eyes as persons advance in life, beginning about the age of forty, and is remedied by *plane*, or better, by *convex* spectacles. The latter is found in youth or young persons, and finds its remedy in *concave* glasses. The far-sighted are unable to see near and small objects, and remove them to an inconvenient distance, while they see remoter objects perfectly well without glasses. The near-sighted are unable to see small objects unless they are brought inconveniently near, and have no distinct vision of remote objects.

"There is a kind of abnormal vision, different from either of these, which is not far-sighted or near-sighted, but in which near, small objects, or larger, distant objects are not seen with distinctness. This imperfection occurs in children and young persons, and is remedied by convex spectacles which are suited to the eyes of persons from sixty-five to seventy years of age. The younger eyes require the older glasses, and with advancing years less convex glasses are required. At the age of forty-five or more this kind of abnormal vision becomes much diminished. As the young use the glasses of the far-sighted, this kind may be called *neo-metropia*. It is evident that convex glasses produce that change in the rays of light which fits such eyes to see distinctly small and large objects at varying distances. This fact proves that there is no

defect in the *adjusting power* of the eyes. The cause, then, is to be sought in the *structure* of the eye. As this kind of eyes does not appear to be too much or too little convex, and as the image is not formed soon enough in the eye, or is too far back, either one or all of the three following may be the cause:

"(1) Too little convexity of the crystalline lens; or (2) its position too near the retina; or (3) its too little density. The second is the probable cause. Spectacles sufficiently convex would bring the rays to a focus, let either or all of the three causes operate, and, with the usual adjusting power of the eye, give distinct vision for near or remoter objects.

"Though this kind of abnormal vision seems not to have attracted attention, for I have found but one *allusion* to it in consulting authors on optics, it is relatively common. In New England and New York more than fifty instances of it have come to my knowledge in the five or six years past. A child of fifteen was able to see distinctly for the first time by the use of his grandfather's spectacles. A young man of eighteen required convex glasses of ten inches focus, while persons of seventy years use those of fourteen to eighteen inches focus. Children often make little progress in study because they do not see objects distinctly, though the defect is not suspected by them, and is utterly unknown to parents and teachers. The knowledge of this subject will make spectacles a still greater benefit to our race."

It will be seen from the above that Prof. Dewey appreciated the nature of hypermetropia with remarkable clearness, especially when we remember that the subject lay outside of his particular field of work, and that his observations were made before the invention of the ophthalmoscope. He observed a large number of cases, and he located the defect in the *structure* of the eye, as distinguished from the *adjusting power*. He went farther, and concluded that the particular fault of structure consisted in a too short distance between the lens and the retina—which is true. Although he does not appear to have been aware of *latent hypermetropia* and of accommodative asthenopia, he nevertheless appreciated some of the sufferings of school-children from their eyes, and predicted the enlarged use of spectacles, which is now an established fact. He was mistaken in thinking that hypermetropia naturally diminishes with advancing age. His remark about plane glasses in connection with presbyopia is probably a compositor's error, for it is not to be believed that he considered such glasses as possessed of any refractive power. It is to be regretted that he did not give the name of the work in which he says he found an "*allusion*" to his subject; but from the title of his article, and from the fact that he has italicized the word *allusion*, it is probable that he derived little or none of his information therefrom.

Whatever value may be attached to Prof. Dewey's observations by those familiar with the subject, they are at least interesting from having been made (apparently) independently, and by a man very busily engaged in other pursuits. They certainly furnish one of the most satisfactory descriptions of hypermetropia—and perhaps the best one—antecedent to that of Donders. If his article had received that attention from our physicians which its importance merited, America might have had some of the honor which now belongs to Holland.

Professor Dewey was born in Sheffield, Mass., Oct. 25th, 1784. He was Professor of Mathematics and Natural Philosophy in Union College for seventeen years from 1810; and from 1850 to 1860 he was Pro-

\* Gross on Foreign Bodies, p. 417.

† Ibid., p. 335.

fessor of Chemistry and Natural Philosophy in Rochester University. He was also a doctor of divinity. In addition to his educational and ministerial work, he made a special study of *sculpes* for forty years, and was an acknowledged authority upon that subject. His death occurred in Rochester, N. Y., Dec. 15, 1867.

## Reports of Hospitals.

### ST. FRANCIS' HOSPITAL.

#### ACCIDENTAL LOSS OF DRAINAGE-TUBES IN PLEURAL CAVITY—SUCCESSFUL REMOVAL BY OPERATION.

SERVICE OF DR. JOHN H. RIPLEY.

(Reported by CHAS. F. STILLMAN, M.D., ASST. HOUSE-PHYSICIAN.)

*Edward Dorsey*, 21, single, Ireland, cotton-spinner, was admitted Jan. 11th, with the following history: A year ago last November was attacked with pleurisy of the left side, which was treated without avail by counter-irritants, and in the following April  $\xi$  xxxi. of clear serum were removed by aspiration. After the lapse of six weeks the effusion was found to be purulent, and an incision was made at the junction of the axillary line and seventh intercostal space,  $\xi$  xxvi. of creamy pus being evacuated, and the wound allowed to heal. In July the incision was renewed and nearly  $\xi$  l. removed; a drainage-tube being inserted, slipped into the patient's pleural cavity the ensuing night. The wound has been draining steadily ever since, but last Christmas he was so unfortunate as to lose another tube in a similar manner, and he entered this hospital Jan. 11th for relief, his attending surgeon having previously attempted their removal without success. On admission, the patient is well nourished, and complains only of occasional pain in the seventh intercostal space, radiating towards the sternum.

The left side of the chest measures two and a half inches less than the right in the xiphoid line, and possesses greatly diminished lateral expansion, with partial effacement of the intercostal spaces by approximation of the ribs. Vocal fremitus on the affected side increased in the mammary, and absent in the infra-clavicular and axillary regions. Extra resonance on percussion in the infra-clavicular region, while in the axillary region there is dulness, which inferiorly becomes flatness, the mammary and infra-mammary regions being slightly extra-resonant.

*Auscultation* reveals very feeble respiration *anteriorly*, with absence of the respiratory murmur over the lower fourth, together with an occasional sticky friction sound. *Posteriorly* in the upper half the respiration is prolonged, with absence of respiratory sound over the lower half and metallic tinkle.

*Jan. 18th.*—It was decided to operate for the removal of the tubes, and accordingly an incision was made by

*Dr. Ripley* in the seventh intercostal space, beginning at a point six and a half inches from the median line and extending posteriorly a distance of four inches. The seventh and eighth ribs were so closely approximated that, at the point where the drainage-tube had been in constant contact with them, a portion of each had necrosed, and it was found necessary to excise a portion of the eighth rib before the proper instruments could be introduced into the pleural cavity. An angular fracture was also found on the seventh rib superiorly, possibly caused by an attempt to force the ribs apart in the operation he sustained before admission. The pleural cavity having been entered after the removal of the dead fragments of bone, its interior was carefully explored by means of uterine forceps, and an Emmet's silver probe so bent at the extremity as to form a hook, and yet so flexible as to offer but little danger of perforating the lung.

After repeated and cautious attempts, the two tubes were found about an inch apart, lying posterior and superior to the incision. The first was found and removed by the forceps, the second by the probe; both being constructed of the material ordinarily used for gum-elastic catheters. The tube retained in the chest since last July measured seven inches in length, was about the diameter of a large goose quill, and somewhat blackened, although but very slightly absorbed, by the fluids in the chest. The other tube measured six inches in length and appeared very bright and fresh. The numerous adhesions and thick layers of fibrine contained in the sac rendered the operation quite difficult. The patient was placed in bed and  $\frac{1}{4}$  gr. morphine injected hypodermically every two hours until midnight, after which he slumbered easily until morning. The next day the temperature did not obtain more than 100° F., and the highest point reached the second day was 100 $\frac{1}{2}$ ° F. in the rectum, since which time it has not exceeded 100°. On the 23d, a drainage-tube was inserted in the lower portion of the incision, the upper having united by first intention, and the patient has since been doing well, the amount of discharge daily diminishing.

## Progress of Medical Science.

**RUPTURE OF THE HEALTHY ŒSOPHAGUS.**—Though cases are sometimes recorded where there has been perforation of the œsophagus in the progress of an abscess, or from the extension of an aneurism, the mechanical laceration due to swallowing angular foreign bodies, the rude introduction of tubes and bougies, the extension of morbid growths, and other similar causes, there does not seem to have been much satisfactory evidence to show that a previously healthy œsophagus may be suddenly ruptured by muscular action. The literature of this curious accident is reviewed by Dr. Fitz, of Boston, with the addition of a case occurring in the practice of Dr. Allen. The patient, a gentleman of thirty-one, addicted to alcoholics, was suddenly attacked, while at supper, with difficulty in swallowing. His face did not become blue, and there was no difficulty in respiration. After an hour's hard exertion, however, he managed by great effort to expel the obstructing material, which was a tough piece of meat about an inch in length, and half an inch in breadth, which was thrown out with noise and force, and the gentleman fell back exhausted, and almost immediately ejected some clotted and liquid blood. General emphysema of the face

and neck set in, with fever, nausea, and tetanic spasms, death ensuing after seven and a half days. Dr. Fitz finds that a study of the cases usually quoted exhibits very defective evidence in their favor, and that in every instance but one the lesion may have been due to post-mortem softening, causing rupture, as often noticed in the stomach. In a medico-legal point of view, these cases are valuable, as showing that muscular action alone can produce the rupture. Soon after the impaction of the foreign body violent efforts are made to expel it. The chest is inflated, and violent efforts are made by the respiratory muscles. In the course of an hour emphysema occurs in the neck and face. Pain is not noticed particularly at first. It is apt to be referred to the emphysematous parts. Auscultation of the œsophagus may clear up some of the difficulties in the diagnosis.—*Am. Journal of the Med. Sci.*, January, 1877.

**TRAUMATIC TETANUS CONTINUING FORTY DAYS—RECOVERY.**—Dr. Chamberlain, of San Francisco, records this remarkable case: A lad of fifteen had his arm caught between two cog-wheels of a printing-press, and sustained a lacerated wound some six inches long, extending above and below the elbow and two-thirds round the arm. The entire cutis and small pieces of muscular tissue were torn out of this space. There was no fracture of bone or dislocation. Everything progressed favorably until the ninth day, when headache and stiffness of the muscles of the neck and jaws set in. On the tenth there were tetanic spasms, returning every hour and lasting from a quarter of a minute to four minutes. The treatment ordered was tincture opii, forty drops every two hours, alternating with hydrate of chloral and bromide of potassium, of each fifteen grains. Bladders of ice, changed every hour, were applied to the neck and back for nineteen days and nights. On the eleventh day there were two unusually severe spasms, but afterwards they averaged, when the patient was awake, thirty-eight an hour, night and day, until the twenty-fourth day, when they began to prove less frequent and gradually decreased until the forty-sixth day, when there were only two. The laudanum was increased during the first twelve days to sixty drops, given in the same intervals as at first, but subsequently the amount was diminished. During the first two weeks of the spasms thin oatmeal gruel, beef-tea, and milk, were the principal articles of nourishment, and were given in the intervals between the spasms, when the muscles of the jaws partially relaxed. Seventy-five days from the receipt of the injury the wound had nearly closed.—*Twelve Med. and Surg. Journal*, Jan., 1877.

**ACUTE TRAUMATIC TETANUS SUCCESSFULLY TREATED WITH CHLORAL HYPODERMICALLY INJECTED.**—The disease was the result of a wound received during a drunken fit, followed by exposure to unusual cold, in a patient of extremely intemperate habits. He was first seen by Mr. Salter two weeks after the accident, and just as tetanic spasms were setting in. It was decided to use hydrate of chloral, and, as he could not swallow, hypodermic injection was resorted to, five grains dissolved in five minims of water being injected into the right arm. During the remainder of the day the injections were practised at intervals of ten, fifteen, or thirty minutes, as the necessity seemed to demand. About one a.m., Feb. 15, a terrible spasm occurred, and ten grains were immediately injected. The treatment seemed to arrest the spasms, and was continued during the day. On the 16th, he had some snatches of sleep, and, though weaker, was able to swallow small quantities of beef-tea and raw eggs with milk.

During the 17th, injections were made sometimes every half hour, and sometimes after an hour or two's interval. On March 2d he was decidedly better; he had about ten spasms and ten injections of from six to ten grains of chloral. From the 3d to the 7th the injections were made at intervals of two, four, or six hours. In a few weeks later he was convalescent, and a year after quite hale and hearty, doing good work as a laborer.—*Practitioner*, Dec., 1876.

**A CASE OF SLOWLY ADVANCING SCLEREMA ATTENDED BY CARDIAC AND GASTRIC DISORDERS.**—Dr. Henley, of London, has had this patient under observation for nearly five years. He is now fifty years of age, of feeble constitution, and a stone-mason by trade. In February, 1872, he was unable to continue his work because the indurations in the subcutaneous tissue of his hands prevented him from closing them. The wrists and forearms are also involved, and there has been a tendency to gangrene at the ends of the fingers. The most marked characteristics of the disease, however, are to be seen on the neck, where the skin in front "forms a thin, hard, rigid plane, gathered into vertical ridges, feeling like knotted cords." On the sides and back of the neck there are red and white patches, the latter of ivory whiteness and opacity. The patient has been becoming feebler gradually, and suffers greatly from stomach derangement and attacks of palpitation. The author believes that the sclerema is merely the direct result of atrophy, *pari passu* of the blood-vessels and lacune and canaliculi of the connective tissue, the atrophy being due to depression of the sympathetic or vaso-motor nerve-power. The whole disease may then be regarded as one in which there is a slowly progressing paralysis of the sympathetic nervous system, the affection being manifested at the periphery by the atrophy of the connective tissue, and nearer the centre by grave disturbances of the circulating and digestive functions.—*Lancet*, Jan. 27, 1877.

**ORCHITIS TREATED BY PUNCTURING THE TESTICLE.**—The following case is of interest as showing the value of puncture, and in view of the attention which this treatment has latterly attracted. A patient, aged 41, was admitted into Westminster Hospital on the 24th of October last, suffering from orchitis, the result of a strain. Mr. Macnamara ran a grooved needle into the testicle, a few drops of serous fluid escaping along the groove. The relief was immediate; the inflammation soon subsided, and the patient left the hospital on November 3d. Mr. Macnamara has not been able to determine in any given case whether the disease was confined to the epididymis or only to the testicle itself. The success obtained in this instance was the rule. In his own person, having injured the testicle some years ago while riding, the testicle was punctured at his own solicitation, and with the happiest results, and he never hesitates to recommend his pupils to adopt the treatment, as there are few diseases in which pain can be so speedily and effectually removed.—*Lancet*, Jan. 13, 1877.

**FUNCTIONAL DISORDER OF THE HEART CHARACTERIZED BY A SLOW PULSE.**—The slowness of the pulse is due, not to severe cerebral lesions, nor to acute meningitis, nor to uremia, nor to poisoning, but to simple functional disturbances. In the great majority of cases it is associated with cerebral disturbances of a secondary nature, such as epilepsy, delirium, or mental and physical prostration. In one of the cases observed by Dr. Flint, the pulse was only sixteen in the minute. Dr. Archibald Heaven's pulse was twenty-four, through during a rheumatic fever it increased to thirty-two.—*Lyon Medical*, Dec. 24, 1876.

# THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, March 10, 1877.

## THE ENDOWMENT OF MEDICAL COLLEGES.

During the late commencement exercises a great deal has been said concerning the endowment of medical colleges. In fact, this has been the burden of all the addresses which have been delivered in this city on the occasions mentioned. So far as a spirited advocacy of the measure is concerned, the outlook towards fundamental reforms in medical teaching is quite promising. The colleges, by this course, virtually acknowledge that the medical shop business is beginning to lose its popularity with the profession, and that something must be done to anticipate the necessities of a near future. The spirit of "glorious rivalry," which is said to exist between the colleges in our large cities, is almost entirely governed by the size of the class and the proportionate increase in income. Of course a given standard is maintained with all, but this is always low enough to meet the mental capabilities of the ordinary matriculant. The colleges say they must have students, or perish. This is the first consideration, and they must obtain them at all hazards. When the faculties are asked the question whether the requirements of medical education are high enough, they frankly answer in the negative, but at the same time admit that any necessary restrictions regarding admission, or extra rigidity in examinations, would be pecuniarily suicidal. And, after all, are we not forced to the conclusion that the shop cares more for the number of customers which it can serve than the quality of goods which it can offer? If the deans of any of the medical schools are asked concerning the prosperity of their respective institutions, the size of the class is always mentioned as of the first importance. No impartial observer would like to believe that the faculties are not entirely independent; but how, under the circumstances, can we prevent such a belief? But this is by the way.

To come back to the original question of endowment,

every one can see that it is the only one which offers any solution for our present troubles. The manner, however, in which these endowments can be obtained brings up many perplexities, and involves the exercise of much reasoning upon expedients.

It would appear to be useless to hope for any help from such as usually bequeath money to public institutions. The charity which the rich have for the medical profession finds a vent in legacies to infirmaries, dispensaries, and hospitals. Medical colleges, as institutions of learning, are beyond the pale of public sympathy. There is really no motive on the part of a liberal giver for taking them into any sort of consideration. We can easily understand how some rich man may in his latter days give to the Church or to charity. His object is to diminish the size of his camel, that it may the better squeeze through the eye of the needle. There is no chance for aid from the government, as it really has no direct interest in the prosperity of any of our institutions of learning. All the endowments which have ever been made to our universities have emanated from those who were specially interested in their prosperity. Most, if not all, of these schools have been under the patronage of some particular religious denomination, and have flourished accordingly. The obligation to give has been a matter of conscience, and, as usual under the circumstances, has been liberally and cheerfully discharged. It was almost a sarcasm for one of the commencement orators, in speaking of the necessity for endowing a particular medical college, to remark that the literary institution of which he was President had within the past few years received donations amounting to over two millions of dollars. This shows the difference between literary and medical schools, and may help us to point a suggestive moral.

The benefit of association with these literary schools naturally occurs to every one. If medical colleges cannot obtain aid of themselves, they may accomplish the same object by becoming parts of a large and prosperous university. And this, after all, appears to be the surest and speediest method of obtaining endowments. The university plan of education, which is developing in this country, will make it necessary for every properly conducted educational establishment to have a medical department. Many of these literary colleges, which are well founded and are constantly receiving large donations, are without facilities for medical instruction. Many excellent medical schools are similarly isolated. It does not need any trick of logic to prove that both would be benefited by a union. A medical school which has gained a reputation by itself would add lustre to any university, and would be a desirable acquisition. It would necessarily yield up its power of individual-government, and be under the nominal control of a university council, but this is a small sacrifice in one direction for great gain in another. The University Medical School, of

this city, is the type of a union to which we refer, and its only misfortune is that the University itself is poor. But the latter may in time become handsomely endowed, and its medical department, which is its brightest and most promising child, must come in for its share of pecuniary benefits. At present it can do no better, unless it denies allegiance to its recognized and legitimate head.

The College of Physicians and Surgeons has not such a direct relation to Columbia College. In the light of prospective endowment, the more the pity. Columbia College is one of the wealthiest educational organizations in the country, and is abundantly able to endow every department of which it may assume legitimate control. The so-called medical department of Columbia College will doubtless be willing to accept endowments, but it does not care to give anything in return. Its peculiar form of government makes it virtually a distinct institution, a close corporation, managed entirely in the interests of its particular faculty. Its board of trustees is as independent of that of Columbia College as it possibly can be. The persistency with which the medical council maintains its so-called individual rights may possibly explain the reason why Columbia College has turned such a deaf ear to its solicitations for the required pecuniary aid. This is certainly a legitimate conclusion in the face of the facts before us.

The Bellevue Hospital Medical College is another institution for which an endowment would not be declined. At present it has no parent, but if it should become a member of the university family of Princeton, its chances of liberal endowment would be reasonably good. We are so well convinced that the best hopes of endowment of our medical schools centre in the plans of union which we propose, that we have no hesitation in recommending them.

We believe that there will be, before many years, one or more medical institutions in this city which will be properly endowed. At present the College of Physicians and Surgeons appears to have the best chance for the consummation of such a desirable result, provided it does not too stubbornly cling to its foolish individuality. In case it continues, however, in its present attitude, there is a possibility that Columbia College will act independently, by founding a medical department of its own, and under the circumstances she should not long delay her opportunity.

The argument that a well-established medical school, by yielding its government to the central council of a university, might suffer from the appointment of irregular and obnoxious persons to medical professorships, is one which certainly deserves consideration. But, in the light of present experiences, this argument has a force which is more apparent than real. It would be directly against the interests of any university to pursue such a course. Its legitimate aim, from first to last, would be to popularize its medical department with the profession,

and the giving of the medical department a voice in professorial appointments would, irrespective of any other consideration, be one of simple policy. The University Medical College has had no trouble in such appointments, and is not likely to have. All questions concerning the competency and availability of the professors in her medical department are settled entirely by the medical faculty. We can hardly conceive the probability of any central council interfering with such a prerogative. If there is shown any disposition so to do there would be the best of reasons for dissolving allegiance to the parent institution. But, as we before intimated, such a contingency is not very likely to occur. It should not certainly of itself be a sufficient excuse on the part of any medical faculty for not making a legitimate effort to effect a proper understanding.

#### MEDICAL LEGISLATION.

THE bill published in another column, referring to the practice of medicine in this State, deserves some attention. On the whole, the bill is reasonable in most of its provisions, and, if the latter can be faithfully and consistently carried out, we shall have solved some of the problems connected with this system of legislation. It is safe enough to rely upon the judgment and capabilities of the different chartered medical societies in settling the question regarding the qualifications which should entitle suspicious individuals to practise medicine; but it is hardly fair for the State to throw the onus of prosecution upon these societies. It is as much in the interest of the State as in the interest of the profession to check the growth of quackery, and, while it is perfectly right for one to help the other in a good work, it strikes us that we have more than our share, more than the authorities have a right to ask from simple citizens. The Board of Censors of this county has done a good deal of gratuitous work in this direction during the past year; but, under the circumstances of time and expense in securing convictions, the office is, on the whole, thankless and unprofitable. How to overcome this difficulty is still an open question, one which we confess our inability to answer. But we are far from trammelling the good intentions of reformers or narrowing the sphere of men who are willing to work for the good of the work itself. We are willing to make the most of what we have or expect to obtain.

On the other hand, another dilemma presents itself in the new bill, and that is the payment of fines to the informers. This of itself will be apt to raise the plea, on the part of the defendants to any action, of interested motives on the part of the plaintiffs, always a very strong plea when it can be at all sustained. But, as we have before intimated, these are some of the problems of medical legislation which only time and experience may be able to solve.

## Reports of Societies.

### NEW YORK PATHOLOGICAL SOCIETY.

*Stated Meeting, Jan. 24, 1877.*

DR. E. G. JANEWAY, PRESIDENT, IS THE CHAIR.

DR. FINNELL presented some gall-stones removed from the body of one of three lunatics who died suddenly on Blackwell's Island under suspicious circumstances. There was nothing peculiar in the specimens, and they were ostensibly exhibited for the purpose of starting a discussion as to the cause of death in those cases.

DR. JANEWAY, by invitation, made some remarks concerning the suspicion of poisoning by picrotxin, but inasmuch as the inquest was not yet completed, he did not desire that they should go on record.

#### FIBRINOUS DEGENERATION OF LUNG TISSUE.

DR. FINNELL also presented a specimen of lung removed from a fireman, who had died suddenly from hæmoptysis. For the past two years, the patient, who was under the care of Dr. Patrick Clark, and was a stout and hearty looking man, had suffered from occasional attacks of hæmoptysis, cough, and other objective signs of pulmonary tuberculosis. One night, on rising suddenly to respond to a fire alarm, the patient coughed up about a quart of blood, and then expired. During his sickness he had been seen by a number of physicians, among whom were Drs. Alonzo Clark, Briddon, Westcott, and Ives. There had been such a difference of opinion regarding the precise nature of the disease, that an autopsy was held.

On removing the lungs there was a total absence of tuberculous deposit, but in its stead a chronic fibroid induration of the lung tissue similar to that observed in the case of the late Dr. Thebaud. Besides this the bronchial tubes were more or less filled with fibrinous deposits. The right lung was adherent from apex to base, the pleural cavity being of course obliterated. The other organs were healthy.

DR. BRIDDON stated that when he saw the patient there were no marked physical signs, but merely a grazing sound of old pleurisy and a few coarse râles on the right side. The pulse was 120, respiration 30-40, and some dyspnoea. The general history was that of phthisis of the non-tubercular variety.

DR. FLINT remarked that the absence of physical signs was in a measure accounted for by the condition of the bronchial tubes.

#### CHANCEROUS ULCERATION OF THE COLON, SIGMOID FLEXURE AND RECTUM, AND STRICTURE OF THE RECTUM TREATED BY LUMBAR COLOTOMY.

DR. HORATIO BRIDGE presented a specimen, consisting of parts of the large bowel taken from a patient who died at Bellevue Hospital, January 10, 1877, of Bright's disease, in the wards of Dr. Stephen Smith, by whose courtesy he was enabled to present the same to the Pathological Society.

The mucous membrane of the anus and of the rectum, about as high as four inches above the internal sphincter, is entirely deficient. About the anus are numerous pit-like depressions, which mark the seat of former ulcerations. At the part corresponding to the top of the internal sphincter, where in life existed a marked stricture, the substitution of fibrous tissue for mucous membrane is most marked, but the calibre of the bowel at this point seems nearly, if not quite, normal. Above this for about three inches, the in-

terior surface of the rectum is mammillated, rough, and harsh.

The parietes of the rectum are greatly thickened by the interposition of fibrous tissue and by hypertrophy of the muscular coats. In the sigmoid flexure and lower part of the descending colon are two ulcerations about an inch in diameter, nearly round in shape, penetrating through the mucous membrane with soft base and edges. Both in the sigmoid flexure and in the descending colon are clearly marked, star-shaped, and linea cæcitrices, both large and small. One of these cicatrices, at about the middle point of the descending colon, has perceptibly diminished the calibre of the bowel by contraction.

In the cæcum and ascending colon neither ulcerations nor cicatrices are found. There is nothing remarkable about the artificial anus, with the exception of a protrusion of the mucous membrane and a superficial ulceration of the same. The transverse colon was not removed.

That the case may be better appreciated, I submit a brief abstract of a paper which I read November 9th, 1875, before the New York Dermatological Society, and which was published in the *Archives of Dermatology*, January, 1876.

"In the spring of 1874, while on duty as visiting physician to the House of Mercy, I had under my care a patient suffering with extensive rectal disease. The case has continued under my care, and illustrates some of the important points in the history and treatment of venereal ulceration and stricture of the rectum.

"The patient, Annie F. M—, is 38 years of age. She inherited a good constitution, and until within five years enjoyed excellent health. About five years ago she contracted venereal disease. Two large, profusely suppurating, painful sores appeared in the vagina a day or two after exposure; were pronounced chancres and canterized; two weeks later they were healed. One month later she complained of an affection of the rectum, characterized by protrusion of mucous membrane from the anus, of pain in that region on sitting and at stool, when loss of blood occurred. These symptoms continued for about a year without treatment, but the patient was not confined to her bed, nor prevented from leading the life of a woman of the town.

"In February, 1874, I first saw the patient, and at that time her condition was as follows: About the anus were a number of flat, pigmented, nipple-like, fleshy protuberances; at the edge of the anus, extending up into the same, were four or five deep fissures, which on dilatation of the sphincter were converted into large non-indurated ulcerations, with deep, dusky red surface, showing no indication of a reparative process. An inch above the anus the mucous membrane was wholly wanting, and in its place a continuously ulcerated, freely suppurating, grayish surface. At the top of the internal sphincter ani was a stricture about  $\frac{3}{4}$  inch in diameter. The patient was markedly reduced in flesh and strength, and suffering greatly from pain referred to regions corresponding to the rectum, sigmoid flexure, and descending colon. She complained of alternating constipation and diarrhoea. From time to time, at intervals of from one to two weeks, there occurred elevation of pulse and temperature, accompanied by increased pain and tenderness in the supra-pubic, left iliac, and lumbar regions, and this continuing for three or four days, subsides with the discharge per anus of a large amount of pus tinged with blood.

"No history of syphilis could be obtained. The

patient had already undergone anti-syphilitic treatment, and subsequently, under my own care, was brought fully under the influence of mercury and iodide of potassium, without improvement in the ano-rectal disease. Various astringent and disinfecting injections were persistently used by my predecessor and myself without satisfactory results. Dilatation of the sphincter was thrice resorted to without good result. The diet was for weeks carefully regulated with the view to reduce to a minimum irritation from the passage of waste matter, without satisfactory results.

"On the 15th of July, 1874, lumbar colotomy was performed with the aid and advice of Drs. Bumstead and Mason, in the presence of Drs. Humphries, Tucker, Watts, Lefferts, and Bronson. The operation proved successful. The feces were passed almost exclusively by the artificial anus; the abdominal pains, previously so severe, ceased almost entirely. The periodical fever and discharge of pus, before so remarkable, ceased entirely. The ulcerations in the rectum took on a healthy condition, and gradually healed.

"A year subsequent to the operation the condition of the patient was as follows: The fissures at the margin of the anus had entirely healed; at the top of the internal sphincter ani was a valvular stricture, which did not permit the passage of the forefinger. No signs or symptoms of ulceration above the stricture could be made out. The injections passed through the artificial anus by the patient herself were discharged at the natural anus free from admixture with pus. The general health of the patient was so good that she was enabled to be up and about, and to engage in light work.

"Subsequently, until the time of her death, the patient was several times obliged to resort to different hospitals for treatment, in consequence of excesses in drink.

"The case, illustrated as it is by the post-mortem evidences of the cure of chancreoid ulcerations, seems of value in showing the effect of lumbar colotomy, to which, as the history clearly shows, the cure was due, after other means had been faithfully tried without success."

DR. BRIDGON referred to a case in point. It first came under his observation six months ago. The stricture was annular in character and tight. Dilatation was resorted to, but without avail; rectotomy was performed, and finally, six weeks ago, lumbo-colotomy was tried. Four weeks subsequent to the latter operation he had occasion to examine the patient on account of the presence of rectal pain, when he was surprised to find the stricture almost entirely gone.

DR. JANEWAY stated that cases not infrequently occurred, which during life presented tight strictures, but in which, at the autopsy, it was very difficult to find them. This was accounted for in part by the absence of reflex muscular contraction, and in part from the destruction of the peri-rectal tissue during the necessary dissection for the removal of the gut. In Dr. Bridge's case, he was inclined to think that the ulceration above the stricture was due to the irritating presence of accumulated feces rather than to chancreoid.

Dr. Janeway lastly exhibited a specimen of empyema, showing the influence of adhesions in limiting the level of the fluid, and also illustrating the fact that pneumo-thorax may result from decomposition of the effusions in the pleural cavity.

The Society went into Executive session.

DR. BARNES, of London, has been elected Associate Fellow of the College of Physicians of Philadelphia.

## NEW YORK MEDICAL JOURNAL ASSOCIATION.

Stated Meeting, February 16, 1877.

DR. CHARLES M. ALLIN, PRESIDENT, IN THE CHAIR.

### THE VENEREAL ULCER, OR CHANCREOID.

DR. F. N. OTIS read an interesting paper upon the above subject, of which the following is an abstract: The venereal ulcer, commonly called chancreoid, was an acute contagious ulceration recognized as resulting from venereal contact. It was a purely local disease, and possessed characteristics which entitled it to be regarded as the highest type of acute ulcerative action. It commonly resulted from the inoculation of the purulent secretion of an ulcer having a similar character. Such purulent secretion, applied to sound integument or mucous membrane, was capable of effecting a solution of continuity, and of communicating to the sore at once its destructive and contagious properties. More commonly the chancreoid was established upon an abrasion of the skin or mucous membrane in the act of coition. The secretion of the chancreoid applied to an abrasion, congestion, inflammation, supuration, and more or less rapid destruction of tissue followed in quick succession, and an ulcer was formed, sharply defined, with ragged edges, pultaceous floor, and secreting pus freely. The chancreoid was seldom single, and occurring under circumstances of good general health, cleanliness, and proper living, it was usually self-limited, and finally terminated in a scar such as was left after an ordinary burn. The secretion, from first to last, was purulent and inoculable, and the sore was capable of being reproduced as readily upon the person bearing it, as upon one free from the disease; but when thus artificially reproduced, it lost, to a certain extent, its contagious property in each successive inoculation, until at last the secretion was no longer inoculable. The tendency of the disease, therefore, under favorable conditions, was towards recovery. When, however, it was attended by unfavorable conditions, such as irregular life, filth, venereal and alcoholic excess, a debayed constitution, etc., the venereal ulcer assumed its most vicious type. It might then assume a high grade of inflammation and become *phagedenic*, or, in other and rarer instances, it might assume a sluggish type, known as the *serpiginous*, and pertinently resist every mode of treatment for years. The extension of the chancreoid action might take place through the medium of the lymphatics and give rise to what was known as the chancreoid bubo. The contents of a bubonic abscess possessed all the peculiar properties of the pus from the original ulcer, and the open bubo took on the appearance of the typical chancreoid. The chancreoid, in its early stages, was easily controlled by proper medicinal measures. The application of any caustic, sufficient to destroy the affected tissue, sufficed to change the venereal into a simple ulcer, and recovery followed without farther treatment than such simple sores required.

In addition to the conditions mentioned as determining the severer forms of venereal ulcer, it was also to be recognized that the lesion present partook, in a great degree, of the activity, whether greater or less, which characterized the lesion from which it was derived. We therefore met with every grade, from the simple excoriation to the sharply defined and most active ulcer. Hence all cases did not require the energetic treatment necessary to arrest the typical venereal ulcer, or chancreoid. The milder varieties re-

quired only mild measures, and simple antiseptic, sedative and astringent remedies might be sufficient to effect a rapid cure.

With regard to the

#### HISTORY OF CHANEROID

it was said to be conceded to be of ancient origin—even to antedate the advent of syphilis, which had been claimed in ancient Chinese and Asiatic records, and to have existed between two and three thousand years before the Christian era. Notwithstanding its early recognition, shortly after the introduction of syphilis into Europe, in 1494, it became confounded with that disease. Its purely local character was lost sight of, and it was subjected to constitutional treatment as a form of syphilis. From the time the confusion of the venereal ulcer and syphilis became complete, all the contagious venereal diseases, gonorrhoea, chaneroid, or venereal ulcer, and syphilis, were practically regarded as identical—requiring the same constitutional treatment. For more than two hundred years forward it was supposed that constitutional syphilis followed gonorrhoea and chaneroid, and hence such patients were habitually mercurialized, but it finally became known that it was only the ulcer with indurated base and edge that was almost invariably followed by general syphilitic phenomena. John Hunter was the first publicly to recognize the value of the induration, characteristic of the venereal sore, which was followed by constitutional syphilis, thus making the first step towards restoring to the different venereal disorders their distinctive individuality. Hunter, however, was led into error, and taught that while the local manifestations of venereal diseases were different their source of origin was identical, and that the variations depended upon some peculiar condition or idiosyncrasy of the individual. In 1798 Benjamin Bell claimed a simple origin for gonorrhoea, and in 1836 Ricord, of Paris, by a series of experiments and observations, eliminated it from among the manifestations of syphilis. Ricord, however, accepted the view of Hunter, and regarded the hard and soft chancre as identical in origin, but made different by individual idiosyncrasies. Bassez, of Paris, one of Ricord's pupils, in 1852, demonstrated that in the soft local ulcer and the indurated infecting chancre, two distinct diseases existed. His observations were made by confrontation; that is, by comparison of individuals, affected by venereal disease, with those from whom the disease had been acquired, and similar observations were made by Clerc, Diday, Rollet, and Fournier in 1856. In 1857 Fournier and Caby, directed by Ricord, proved that, in all cases of chaneroid, the type of the ulcer remained unchanged in passing from one individual to another.

M. Clerc, although accepting and confirming the observations above alluded to, claimed to have demonstrated that the chaneroid was the product of an inoculation of the syphilitic virus upon persons then or previously affected with syphilis, thus asserting a unity of origin for the two diseases. The same observer also claimed that, although as a rule the chaneroid thus originated, transmitted only chaneroid, yet on being inoculated upon a healthy person, it was capable of reverting to its original type and of communicating syphilis.

Rollet and others, on the contrary, held that the chaneroid, the soft local sore, and the chancre, the initial lesion of syphilis, were separate and distinct diseases, and had their origin in separate and distinct influences. Thus the two schools, the unicists and the

dualists, were initiated. Lee, of London, Böck, of Christiania, and others succeeded in producing the typical chaneroid upon persons syphilitic and non-syphilitic by inoculation of pus from an irritated syphilitic chancre. The degree of irritation required was that sufficient to produce free purulent secretion, and such sores were inoculable in successive generations upon persons quite free from syphilitic taint, and progressed in all respects like the ordinary venereal chaneroid. Next it was found that when the superinduced irritation subsided, the secretion was no longer purulent; it was no longer auto-inoculable. It was concluded, therefore, that the property of inoculability or contagion depended upon a peculiar action resulting from the persistent irritation of an already diseased surface. The fact that such a sore could be established upon persons free from syphilitic antecedents, and not be followed by constitutional syphilis, demonstrated that it did not necessarily depend upon the syphilitic principle. Then came a series of experiments made by Pick, Koelner, Kaposi, and others, to ascertain the effect of inoculations of pus from simple lesions on persons free from syphilitic taint. The result had been formulated by Kaposi as follows: "Affections in non-syphilitic persons which are of slight virulence, and the secretions of which are not inoculable, can be made to produce an inoculable secretion by the application of an irritant." Reference was also made to the paper read by Dr. Bumstead before the Centennial Congress, in which was reported the case of Dr. Wigglesworth, of Boston, who in 1866, while in somewhat impaired health, inoculated himself with the pus from a simple acne pustule. Three generations of ulcers were established, and left as many distinct cicatrices. The experiment was under the personal observation of Prof. Zeissl, of Vienna. Reference was further made to the writings and experiments of Bäumlér, John Morgan, and Vidal. Personal observations had shown Dr. Otis that the muco-purulent secretion from a non-specific nasal catarrh would sometimes produce excoriation of sound cuticle; that contact with secretions from non-specific leucorrhoeas would sometimes promptly cause pustular eruptions upon the preputial mucous membrane, more or less rapid in development, and progressing according to the degree of the acidity of the fluid causing them—in some instances scarcely more than sero-purulent vesicles, in others so vicious that their development and progress did not differ appreciably from the typical chaneroid. Reference was then made to several illustrative cases.

From all that had been adduced it seemed to Dr. Otis that it must be conceded the quality of pus was variable, and varied according to the circumstances under which it was produced, and the condition of the person on whom it might be inoculated. A low condition of the general system, from any cause, predisposed the tissues to take an ulcerative action and to elevate the attendant purulent secretion to a point of contagiousness. When, therefore, it came to be considered that the most frequent habitat of the venereal ulcer or chaneroid was in localities where venereal excess and every kind of debauchery ran rampant; when to that was added the potent elements, syphilis, scrofula, filth, and irregular life, and also that chaneroid was by far the most frequent, as compared with syphilis, among the debased and dissolute, the conclusion was regarded as inevitable that chaneroid was of necessity a self-engendered disease, possessing no specific virus, but acquiring its power for destruction and contagion through various diseased conditions, or through the reckless stimulation and vitiation of benign natural processes. The distinction between

chancre and the initial lesion of syphilis, at the outset, was often impossible, and never possible unless the source of origin was known. The leading feature and characteristic of chancre was a *ulceration*, that of the syphilitic lesion one of rapid *proliferation*. The latter was a *builder* of tissue, the former a *destroyer*. The only method of determining whether a given chancre or other lesion was to be followed by constitutional syphilis (unless its source was known) was to wait at least one full month after the exposure, even though during that time the suspected lesion—possessing all the characteristics of the typical chancre—had fully healed. The frequent association of chancre with syphilis would never lead to mistaken identity if it was borne in mind that syphilis was always, in all its manifestations, the result of a process of *proliferation*, of exaggerated growth. The only product of syphilis, from the initial lesion to the growing tumor, was an excessive accumulation of tissue-building cells. Chancre, on the other hand, from its inception to its cicatrization, was a process of *destruction* of tissue. It could be claimed, therefore, that syphilis and chancre were always and only in relation to each other as life to death—each the highest type of its own peculiar action.

The paper being open to discussion—

Dr. F. R. STURGIS remarked with reference to the anti-inoculability of non-specific pustules, such as acne, ecthyma, etc., that the experiments mentioned in the paper had been made upon persons who, at the time, were the subjects of debility, and that it was probably the debilitated condition which favored the development of the peculiar ulcers obtained; whereas, with the inoculation of chancre-like ulcers, it made no difference, so far as debility was concerned. And it was only after repeated inoculations with the same virus had been made that there was a seeming immunity obtained; but they could be reproduced with new virus in fresh soil as well as on the person bearing them.

The inoculation for acne, ecthyma, herpes, etc., had never been successful, unless the person upon whom the inoculation had been made was in a condition of debility. To inoculate healthy persons and produce an ulcer, the pustule must first be irritated, thereby introducing a new element into the experiment.

Dr. Sturgis had inoculated both himself and the persons bearing the lesion, from croton-oil pustules, acne, scabies, and pemphigus, without the element of irritation being introduced, and on no occasion had the least effect been produced.

His experiments were performed upon those persons among whom they would be most likely to be successful, *i. e.*, hospital and dispensary cases, because they were surrounded by unfavorable conditions.

With regard to the statement made by Dr. Otis, that chancre was probably not due to a special virus, but rather to unfavorable surrounding conditions, filth, excesses, irritation, etc., Dr. Sturgis believed that more evidence was required upon that point before it could be decided positively. Whether there was a real virus or not, we did not know what it was, and could, judging from its fruits, only say that it was some irritant which produced its peculiar effects.

Dr. Sturgis referred to a case mentioned by Dr. Otis in which the patient, not particularly strong, had been inoculated, with the probable production of a chancre, and claimed that in such patients it was found that herpes would assume all the characteristics of a superficial chancre, producing in the person a lesion carrying out all the semblance of a chancre, except

that it was believed, if herpetic, to be incapable of inoculation either on the bearer or another; and here he believed inoculation had not been practised.

From the appearance of the two lesions one could not tell whether he had to deal with a superficial chancre or a herpetic vesicle; their semblance was such as to render it impossible to distinguish them. Dr. Sturgis believed that more light was required before it could be decided that acne pustules were inoculable in the same sense as chancres.

Dr. Otis remarked that he wished to be understood as saying that sores on inoculation communicated like sores; that a sore having a low grade of inoculability communicated one having a like low grade of inoculability, if any at all; and that the chancre in its typical state was a sore exposed to all the irritating influences which could be conceived of, and had thus been raised to its present degree of active virulence, but that it lost such activity by repeated inoculation.

It seemed to Dr. Otis that Dr. Sturgis had very happily supported him in the statement that sores which were engendered in weakly individuals produced on inoculation similar sores in persons also debilitated, while no effect was produced when the secretion of the same sores was inoculated on healthy persons. From that fact it became evident that the contagious property was, to a certain extent, dependent upon the condition of the individual affected, and that debility was one of the known factors in producing the inoculable property in purulent secretions. It was further claimed that vinous and venereal excess, uncleanness, etc., were among the other factors which went to make up the degree of virulence that characterized any given local contagious venereal lesion.

If we were compelled to wait until all the exact conditions obtaining in the production of typical chancre were present in our experiments, the subject, of necessity, must remain open forever.

We were obliged to judge by analogy and by comparison; it was impossible to have the exact conditions, but it was sufficient that we were able to recognize the fact that there was a great variation in the virulence of such sores; and that the virulent sores continued to produce the same kind because the influences were such as to raise it to the highest point of activity. There was an almost fixed condition in each chancre, which was propagated to the next sore, perhaps, however, somewhat diminished in virulence. There was almost as much reason to believe in such difference in venereal sores as, for example, in the differences in the series of chemical compounds from nitrous oxide, laughing-gas, to nitric acid; typical chancre, in the variations, being made by the addition of one part of oxygen to each lower member of the series. So it seemed to Dr. Otis that there were venereal ulcers the secretion from which was bland, irritating scarcely any, if at all; but the greater the proportion of excitement thrown in through excesses, etc., the more active they become, until finally the activity was raised to such a height as to cause a rapid destruction of tissue.

Dr. STURGIS remarked with regard to the question of irritation that the sore usually produced the same characteristics when carried to those who were perfectly free from disease. Take, for example, a pustule of acne and the initial lesion of syphilis, and, without irritation, make an anti-inoculable sore for both. Chancres were not produced in either case. Carry to fresh subject from the acne pustule, and an abortive pustule was produced; but from the initial lesion of syphilis, syphilis was obtained.

It was in the matter which was carried, and not in

the subjects themselves, that the variation in results was produced.

When the inoculative was carried to the first subject, without irritating the pustule of acne, nothing was obtained; but with the primary lesion of syphilis, if irritated, a local lesion might be produced by inoculating the bearer of the syphilide, but was it a chancreoid when carried to some one else?

Dr. Fox coincided with Dr. Otis in the opinion that a chancreoid might be of an exceedingly mild type, or vary all the way to the typical inflammatory sore; that by means of local irritation, uncleanness, excesses, etc., it might be raised from any grade to a sore in the highest degree inflammatory; and that in that form it might be transmitted to another person.

Dr. Dupuy remarked that success in obtaining sores by inoculation depended very much upon the age of the pus employed. Inoculation might be made at one time without success, and at another successfully, according as the pus was younger or older. It had been ascertained that the real virus consisted of solid particles, and that when these were present the pus was capable of producing a sore by inoculation, and when they were absent inoculation was impossible.

After a brief discussion touching the history of syphilis, by Drs. J. C. Peters, Sturgis, Dupuy, and Otis, the Association adjourned.

## Obituary.

GURDON BUCK, M.D.,

NEW YORK.

THE painful anxiety concerning the health of this distinguished surgeon has at last culminated in his death. This sad event occurred on the morning of March 6, ending a long and useful career. He was born in this city May 4, 1807. After a very careful and thorough preliminary education, his parents destined him for mercantile pursuits, in which for a time he became engaged in this city. Such not being congenial to his tastes, and having an ardent desire to study medicine, he afterwards became a student in the office of the late Dr. Thomas Cook, and was formally matriculated in the College of Physicians and Surgeons, graduating from that institution in the spring of 1830. Immediately after this he entered the medical division of New York Hospital, passing through the usual grades of internship.

Naturally ambitious to improve every opportunity for study and practice, he became one of the attending physicians to the N. Y. Dispensary, then in the infancy of its usefulness. While serving in that capacity an accidental circumstance determined his future course. A child was brought to him from Westchester, suffering with stone in the bladder. The desire to relieve the sufferer prompted a thorough study of the case. So interested did young Buck become in this study that he determined to be a surgeon rather than a physician. Having made up his mind upon the subject, he appreciated his opportunity, and operated upon the patient. From that time a new field was opened before him—a field to the successful cultivation of which he devoted his best energies.

In 1835, with a desire to take advantage of extra facilities for study abroad, he left this country in a sailing vessel, dividing up an absence of two years in the medical centres of France, Austria, and Germany. On his return to New York, in 1837, he was appointed Attending Surgeon to the New York Hospital, which

position he held up to the time of his death. On the death of Kearney Rogers he was made Attending Surgeon of the New York Eye and Ear Infirmary, which position he occupied for nine years. When the St. Luke's Hospital, of this city, was being founded, he was the trusted adviser of the managing board, and the subsequent perfect administration of this noble charity has been in no small degree due to his individual exertions. After its organization he was appointed Attending Surgeon, the duties of which position he continued to discharge until 1868, when he resigned to accept a similar connection with the Presbyterian Hospital. He remained in active connection with this institution until a few months ago, when his rapidly failing health rendered him unfit for duty.

As a surgeon Dr. Buck was remarkable for boldness in operating and for thoroughness of detail in after-treatment. His patient study of his cases was one of his peculiar traits. To cases of fractures he was particularly attentive, spending not infrequently the greater part of the day in the wards of the New York Hospital in dressing them. As a result of such painstaking he was enabled to revolutionize the prevailing system of treatment. To his personal study and exertions were due, more, perhaps, than anything else, the enviable reputation which this hospital so long maintained for the brilliant results of this class of injuries. The improvements which he made in the then existing apparatus are matters of surgical history. His method of treating fractures of the thigh by the weight and pulley was at once recognized by surgeons throughout the civilized world as the establishment of an original principle of the utmost value.

Dr. Buck was not only a bold, but an original operator. The various capital operations which are described in the periodical medical literature of the past thirty-five years abundantly prove the latter statement. Among these, what is now known as Buck's operation for oedema of the glottis holds a deservedly high rank. But in no department did he gain more laurels than in antoplasty surgery. His devotion to this branch, during the latter part of his life, amounted to a passion, and his marvellous successes roused in him an enthusiasm which mocked the increasing infirmities of his age and his rapidly declining health. His work on "*Contributions to Reparative Surgery*," issued only within the last year, fully embodies his remarkable experience, and may be looked upon as the crowning effort of a most notable and distinguished career.

During a second visit to Europe in 1836, Dr. Buck was married to Miss Henrietta E. Wolff, of Geneva, Switzerland, who survives him. He also leaves three sons and two daughters. Two of the sons, Drs. Albert H. and Francis D. Buck, are physicians, and the third, Gardon S. Buck, is a lawyer—all being engaged in practice in this city.

Dr. Buck was a Fellow of the Academy of Medicine from its organization, and was once its vice-president. He was also a member of the New York Pathological Society, of which he was at one time president, and of the County Medical Society, the State Medical Society, and the American Medical Association. For varying periods in the last thirty years he had been a trustee of the College of Physicians and Surgeons, the New York Eye and Ear Infirmary, the New York Dispensary, and the New York Ophthalmic and Aural Institute.

For the past year or more his health began sensibly to decline, and grave symptoms appeared, which were for the most part referred to kidney trouble. Finally the symptoms of uremic poisoning became

more and more marked, until he sank into coma, in which state he quietly passed away.

He was faithfully and lovingly attended to the last by his trusted medical friends and advisers, Drs. James R. Leaning and Alonzo Clark.

As a man, Dr. Buck was noted for his sterling integrity of character, his high sense of professional honor, his consistent Christianity, his charity to the poor, and his quiet devotion to his family. Can more of good be said of any one?

### ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from February 25 to March 3, 1877.*

BENTLEY, E., Asst. Surgeon. To report to the commanding officer of the 16th Infantry, Custom House, New Orleans, for temporary duty with that regiment. S. O. 31, Dept. of the Gulf, Feb. 20, 1877.

PAULDING, H. O., Asst. Surgeon. Assigned to duty with Battalion 2d Cavalry, in the field. S. O. 24, C. S., Dept. of Dakota.

BROWN, P. R., Asst. Surgeon. Assigned to duty with Battalion 2d Cavalry, in the field. S. O. 24, C. S., Dept. of Dakota.

THE PRACTICE OF MEDICINE IN THE STATE OF NEW YORK.—*Assembly* 32, January 3, 1877. Introduced by MR. MITCHELL, read twice, and referred to the Committee on Public Health, and ordered printed.

AN ACT to regulate the practice of medicine in the State of New York.

SEC. 1. Every person practising medicine or surgery in the State of New York shall record his name in full, the place of his residence, the name of the college or society granting him a diploma or license, together with the date of such diploma or license, in a book kept for said purpose by the Secretary of the Board of Health of the city of New York, where such practitioner resides in said city; and where such person so practising is not a resident of said city, he shall record his name in full, the place of his residence, the name of the college or society granting him a diploma or license, together with the date of said diploma or license, in a book kept for said purpose by the clerk of the county in which such person so practising resides, and a fee of twenty-five cents shall be paid to the Secretary of the Board of Health of the city of New York for each name entered in said book kept by him, by the person entering said name, and a like fee to the clerk of the county for each name entered in said book, kept by him, by the person entering said name; and the Secretary of the Board of Health of the City of New York and the

clerk of each county in the State are required to keep each a book for the entry of names as herein provided, and such books are to be kept open for the inspection of all who desire to examine them during office hours.

§ 2. Every person practising medicine or surgery in the State of New York, excepting licentiates of a chartered medical society or graduates of a chartered school, is required to obtain a certificate from the Board of Censors of some one of the several State, county, or district chartered medical societies, which certificate shall set forth that said Board of Censors have found the person to whom it was issued qualified to practise all the branches of the medical art.

§ 3. The Secretary of the Board of Censors of any one of the chartered medical societies mentioned aforesaid, may summon, personally or by mail, all persons practising medicine or surgery, excepting licentiates of a chartered medical society or graduates of a chartered school, and excepting those who have certificates issued to them in accordance with section two of this act, to appear before the Board of Censors, of which he is Secretary, at a certain time and place within thirty days after the receipt by such person of such summons, and undergo an examination as to their qualifications to practise medicine or surgery.

§ 4. It is hereby declared a misdemeanor for any person to practise medicine or surgery in this State unless authorized to do so by a diploma from a chartered school, or a license from a chartered medical society, or a certificate issued in accordance with section two of this act, or to practise medicine or surgery under a diploma, license, or certificate illegally or fraudulently obtained, and any person found guilty of such misdemeanor shall, for the first offence, be fined not less than two hundred dollars nor more than three hundred dollars, and shall be imprisoned until such fine be paid, and for any subsequent offence not less than four hundred dollars nor more than six hundred dollars, and shall be imprisoned until such fine be paid, subject, however, in both cases to the terms of limitation prescribed by the provisions of chapter sixty-one of the laws of eighteen hundred and seventy-six. And all such fines shall be paid to the treasurer of the medical society the president of which makes the complaint.

§ 5. Proceedings under section four of this act shall be instituted by the president of some one of the medical societies mentioned in this act, by his written complaint, sworn to by him before a police justice or notary public.

§ 6. The act of May 11th, 1874, regulating the practice of medicine and surgery in the State of New York, and all acts and parts of acts inconsistent or in any wise conflicting with the provisions of this act, are hereby repealed.

§ 7. This act shall take effect immediately.

ALUMNI ASSOCIATION OF THE COLLEGE OF PHYSICIANS AND SURGEONS.—The annual dinner of the Alumni Association of the College of Physicians and Surgeons, given on the evening of March 2d at Delmonico's, was largely attended, and proved a thoroughly enjoyable affair. The dinner was held in the large dining-parlor, and presided over by Prof. William H. Draper, the President of the Association. After the elaborate menu had been disposed of, the following toasts were responded to respectively as follows: Our Alma Mater, by Prof. J. C. Dalton; Columbia College, by Prof. Chandler; the Clerical Profession, by Dr. John Cotton Smith; the Legal Profession, by Hon. Joseph H. Choate; our Sister Colleges, by Prof. D. B. St. John Roosa, of the Uni-

versity Medical College, and by Prof. A. B. Crosby, of the Bellevue Hospital Medical College; concluding with a response by Prof. F. Delafield to "the Pet of the Alumni Association," the Endowment of a Pathological Chair.

**COLLEGE OF PHYSICIANS AND SURGEONS.**—The seventieth annual commencement of the College of Physicians and Surgeons Department of Columbia College occurred on the evening of March 1st, at Steinway Hall. Upon the platform were the Presidents of Columbia College and the College of Physicians and Surgeons, the Faculty of both institutions, and a large number of prominent physicians. The exercises were opened by prayer by Rev. Dr. Sullivan H. Weston, after which degrees were conferred upon the graduates, numbering 118, the Hippocratic oath being at the same time conferred upon them by Prof. F. A. P. Barnard. At the conclusion of this ceremony the graduates were addressed by President Alonzo Clark, who reviewed the progress of medical science from the earliest ages to the present time. Diplomas of honor were next awarded to Henry L. Elsner, William B. Goldsmith, William S. Halsted, Frank A. Langworthy, Daniel M. MacMartin, Charles N. Raymond, Thomas L. Stedman, John W. Sutton, and L. D. Woodbridge, special prizes of \$100, \$50, and \$25, for special competitive examination being awarded as follows: First prize, \$100, to William S. Halsted; second prize, \$50, to Thomas L. Stedman; third prize, \$25, to Henry L. Elsner; and another of same amount, to John W. Sutton, both gentlemen having tied in their competitive examination. The special prize of \$250, offered by the Alumni of the college to the author of the best essay, was next awarded to Dr. George B. Fowler, a graduate of the class of 1871. The valedictory address was delivered by George A. Edwards, M.D., who emphasized the importance and responsibility of the physician's calling, and urged his classmates to enter upon their professional career with the resolution of adding something of value to the medical science of their day, and not merely of taking advantage of what their predecessors had left them. The speaker was followed by Bishop A. Cleveland Cox, who delivered a closing address to the graduates, in which he considered at length the obligations of physicians as professional men, and their duty to society. At the conclusion of the address the audience were dismissed with the benediction.

**THE CONDITION OF THE MUNICIPAL HOSPITALS.**—The fifth annual meeting of the State Charities Aid Association was held on the afternoon of March 1, in Municipal Hall, No. 67 Madison Avenue. There was a large attendance, principally of ladies. Mr. Howard Potter, in the absence of the President, acted as Chairman. An election for officers for the ensuing year resulted as follows: President, Miss Louisa Lee Schuyler; First Vice-President, Howard Potter; Second Vice-President, Mrs. William B. Rice; Third Vice-President, Frederick Law Olmstead; Fourth Vice-President, Theodore Roosevelt; Fifth Vice-President, Mrs. C. R. Lowell; Treasurer, John Crosby Brown; Corresponding Secretary, Mrs. Joseph Hobson; Assistant Secretary, Mrs. S. E. Minton. The Treasurer's report showed the total receipts for the year to have been \$2,687.90, and the expenditures \$261.75, leaving a balance on hand of \$2,426.15. Mr. Potter expressed the hope that during the coming year the Association would more truly than it had previously done earn the title of a State society by enlarging the scope of its work. The reports were then read of the various committees of the Association. The most interesting

of these was that of the Hospital Committee concerning Bellevue and other hospitals under the management of the Commissioners of Charities and Correction. The committee say:

"The administration of the public charities has properly nothing to do with politics, but the Department of Charities and Correction is merely a political machine. Not that the appointments are all bad; some are very good; but the Commissioners are hampered by political considerations which ought not to influence them. For example, the committee asked for the removal of a certain incompetent official, and were told that no one in the department was powerful enough to effect it. This was two years ago, and the incompetent person still retains the post. In respect to nursing, the public hospitals are in advance of the private hospitals of New York. The training-school at Bellevue has had exceptional advantages in the attention it has received from its Committee of Management. At Charity Hospital great progress has been made; the women are of a better class, and anxious to learn, but they should have a matron at their head responsible to the physicians for their work, and to the Chief of Staff for their discipline. At present the Chief of Staff is called upon to settle disputes among the women; his labors are arduous and discouraging, but, in spite of obstacles, he has effected many improvements. The heating and ventilation of Charity and Bellevue are notoriously bad. The State Charities Aid Association would have furnished a plan prepared by experts for a new ventilating and heating apparatus for the hospitals, but the Commissioners did not consult them, and offered the contract for putting one in at Bellevue to the lowest bidder. The work, now completed, is a total failure. The bad condition of the plumbing work aggravates the defects of the ventilation, the pipes are often out of order, and on January 20th thirty-two of the faucets were leaking. The ventilation at Charity Hospital is, to the senses, even worse. The foul air from the cellar, through the centre of which the main sewer passes, is heated and carried into the wards. The ventilating flues open into the attic, instead of being carried into the outer air. When the hospital was built it was intended that fans should be placed in the cellar, to supply fresh air, but they have never been introduced. The windows of the cellar are not kept open, because, it is said, it would increase the consumption of fuel to bring in fresh cold air to be heated. The committee urges the necessity of building maternity pavilions on Blackwell's Island, to relieve the overcrowding of Charity Hospital. A small lying-in hospital is much needed in the city, and the committee have urged the Governors of the Society of the New York Lying-in Asylum to open one. The Ninety-ninth Street Hospital, which is well cared for, is not required, since there are several large hospitals in the vicinity which would be glad to take the patients. The committee recommend that it be closed, and that the funds for its support be applied to a small lying-in hospital."

**BOGUS DIPLOMAS.**—Since our last issue we have had forwarded to us by hospital stewards more copies of the circular of the bogus diploma agent at Buffalo. It would seem that the agent in question has miscalculated the character of his customers. He deserves, however, in a business way, some credit for his enterprise, as from present indications every hospital steward of the army has been addressed upon the subject. Again we call the attention of the Erie County Medical Society to this shameful and barefaced swindle.

## Original Communications.

### PRACTICAL POINTS IN THE ELECTROLYTIC TREATMENT OF CYSTIC AND FIBROID TUMORS.\*

By GEORGE M. BEARD, M.D.,

NEW YORK.

THE department of electro-therapeutics that relates to the electrolytic treatment of tumors appears to increase rather than diminish in interest. The necessary difficulties that attend the introduction of a radically new mode of treatment, and one requiring special apparatus and experience, in a severe variety of disorders have, it is true, retarded, but have not entirely arrested, the popularization in the profession of electrolysis, or decomposition by means of electricity, either as a last resort, or, in some cases, as the first and best method in both benign and malignant tumors.

These difficulties and discouragements would, I am persuaded, be fewer if the true principles at the basis of this method of treatment were well understood by those who employ or recommend it. In treating tumors by electrolysis intelligently, it is needful to know both the laws of electro-physics in general and their application to the tissues of the body in particular. A knowledge of the nature of tumors, also, so far as we can claim to know their nature, certainly a familiarity with their clinical history, is not to be dispensed with.

In regard to the electrolytic treatment of malignant tumors, these conclusions are justified by experience up to the present date:

*First.* In all or nearly all cases the pain can be relieved, even in the latest stages.

This may be accomplished oftentimes by simple external galvanization without electrolysis.

*Secondly.* In a certain proportion of cases taken early, malignant growths may be temporarily or permanently arrested, so that patients are free from pain and from all severe annoyance, although the tumors are but little or not at all diminished in size.

A number of cases of this kind have been under my care, and some of them are yet under my observation.

One case in particular I recall, of a lady who, for thirteen years, has carried what is supposed to be a cancer in the breast, which five years ago seemed to be taking a new start; but external galvanization alone appeared to arrest the progress of the malady, and the patient is living to-day, although the tumor exists and is not at all diminished in size.

In another case of malignant cystic of the breast, electrolysis caused evacuation of the fluid and subsequent shrinkage of the tumor to about one-third of the original size, at which point it has remained for three years, causing, at the last accounts, no annoyance.

In cases like the above there is room for errors in diagnosis, and also the consideration that some tumors that prove to be malignant, even when not treated, are stationary for years, is to be noted. In the cases here referred to, however, there was no difference of judgment among the many surgeons who saw them, and in the latter case an operation was earnestly and unanimously advised.

*Thirdly.* Malignant cystics, like epithelioma, may be treated successfully, in many cases, by electrolysis of the base, the body of the tumor being neglected.

This method of treatment I have elsewhere described in detail, and only refer to it here as a measure that may be resorted to in cases where it is feasible, when electrolysis of the body of the tumor in the ordinary way does not accomplish what we wish.

My special purpose in this paper is, to speak of benign or non-malignant cystics and fibroids—that is, cystics or fibroids which, when once thoroughly removed by an operation, do not return—in their relation to electrolysis.

While tumors of this kind may occur in various parts of the body, they are particularly common in the ovaries and uterus; but the same general principles apply to the treatment whatever the locality may be.

The *first* practical point I would enforce is, that the object of using electrolysis in cystic tumors is not the decomposition of the fluid constituents, but the stimulation of the secreting surface so as to prevent further secretion and aid absorption.

The mere evacuation of the contents of cysts in the ovaries, or in other parts, may be accomplished by tapping; but the thing needed is to prevent a refilling of the sac. In the electrolysis of cystics it sometimes happens that the fluid flows out where the negative needle is inserted during or directly after the operation; but this discharge of the contents, and consequent shrinkage of the tumor, is a temporary matter, unless the effect of the operation has been to prevent the morbid secreting process. The decomposition of the fluid contents by the action of the electricity may be brought about provided the current be sufficiently strong and the operation long enough to bring all the atoms under the influence of the current; indeed, the decomposition sometimes takes place so rapidly that the resulting gases cause swelling and tension of the sac, and the hydrogen and fluid flow out together in the track of the negative needle; but that process is an incident to the operation rather than the operation itself. In hydrocele, for example, which is a type of this kind of tumor, a radical cure is sometimes effected by electrolysis, even when scarcely any decomposition takes place. In a case of hydrocele in a child, I inserted the negative needle but for a moment, and then was obliged to withdraw it on account of the struggles of the patient, and the operation was deferred for another day. When the day arrived the patient was well. Many of the failures with electrolysis have been owing to misconception on this point. In operating on this class of tumors I pay little heed to the decomposition, but manipulate one of the needles, if possible, so that the inner secreting surface may be acted upon. The stimulation of the secreting surface in this way seems to have a two-fold effect—it prevents secretion and also causes absorption, both of which results are desirable.

A physician of Chicago, Dr. Peck, who makes much use of galvanic baths, wrote me several years ago that he had cured a case of incipient ovarian tumor by the bath alone, no needles having been used. This is by no means incredible; for in the warm bath the skin becomes so saturated with water that its conductivity to electricity is very greatly increased, and it is conceivable that the stimulus to the secreting surface thus obtained might be sufficient to cause the disappearance of a cystic tumor of moderate size. Yet further it has been shown that the mere puncture of tumors may be followed by their disappearance. Dr. C. L. Mitchell informs me that he has had an experience of this kind. In cases of this sort, occurring rarely and accidentally, however,

\* Read before the N. Y. Medical Journal Association, Feb. 2, 1877.

there may be two sources of error—coincidence and mental influence. Tumors—not usually cystic or fibroid, however—sometimes disappear or diminish in size of themselves, or at least without any apparent cause. At one time I had under my care a patient with a very large fibroid tumor. Under electrolytic treatment, carried eventually to the point of suppuration, there was a considerable diminution in the size of the tumor, and very great relief of many of the accessory symptoms; but beyond a certain point nothing could be done. About one year after the treatment was suspended the tumor grew very much smaller of itself, while nothing was being done for it, and the patient has been much better ever since. One year ago I saw a lady who reported that she had at one time a tumor which prominent surgeons of Philadelphia, New York, and other cities pronounced to be ovarian, and an operation by electrolysis was urged. The woman was very ignorant and superstitious, and, declaring that she would rather die a natural death than be killed by the doctors, went off to one who cured by the "laying on of hands" and other flummeries. The result was speedy and satisfactory; the tumor disappeared, and at the time I saw her she had been free from it for several years.

Facts and considerations of this kind should be borne in mind, since they aid us in explaining some, at least, of the inconsistencies of the results of experiments in this department.

A second practical point is, that the object of electrolysis of fibroids and the solid walls of cysts is not so much the direct and immediate destruction of tissue as the general modification of nutrition. This modification in nutrition is the result in part of the stimulating action of the current on the tissues, causing absorption, in part of the coagulation of the albumen, and in part very likely of the change in the innervation produced by the action of the currents on the nerves of the part.

It not unfrequently happens that goitres, for example, go down perceptibly after one or two electrolytic operations, in which there has been little or no destruction of tissue. In such cases a modification in the nutritive processes must take place not only near the points of insertion of the needles, but in all parts of the tumor, and very likely in parts that are not traversed by the currents at all, but are affected only indirectly, perhaps reflexly, through the nerves. Indeed, the best results of electrolytic treatment in cystics and fibroids are not due to the electrolysis at all, but to the action of the electricity without regard to electrolysis and independent of it. In the treatment of *navi*, on the other hand, the chemical action of the current—electrolysis—is the one and only thing sought for.

A third practical point in the treatment of tumors of this class is, that batteries in which the elements are united in series, that is, for "tension," should be used rather than batteries in which the elements are arranged in the multiple arc, or the so-called "quantity" battery.

In electrolytic operations, as in all applications to the human body, great resistance is encountered, though very much less when the skin is punctured and the needles are near together than in applications on the surface with electrodes far apart. It follows from the law of Ohm, which is to electro-physics what gravitation is to astronomy, that in applications to the body—central and local galvanization, as well as in electrolysis proper—batteries in which the elements are arranged in series are required, since the external resistance must always be considerable; and against

great external resistance large cells send but little more electricity than small cells.

When in electrolytic operations the needles are very near together, and in a warm saline fluid,\* such as is sometimes found in cystic tumors, the resistance may be so slight that electrolysis may take place very rapidly with two or three large cells of a quantity or galvano-cautery battery. With Byrne's galvano-cautery battery, for example, electrolysis of a mixture of water and sulphuric acid goes on with violence when the electrodes are a fraction of an inch apart. But in the electrolytic treatment of cysts such powerful action is not needed, and if it were there is no occasion for the use of a quantity battery in order to obtain it. In the electrolysis of solid fibroids of the uterus there must always be a large amount of resistance, even when the needles are brought near together; for the tissues are hard and comparatively dry, and against resistance of this kind a number of large cells will send no more electricity than a number of small cells; for the reason which Ohm's law mathematically explains, that the potential electricity in the large cells—that is, the electricity which they are capable of generating—has no chance to become actual electricity: the resistance is so great that it cannot, so to speak, get out; it is consequently locked up in the atoms of the fluids and metals of which the battery is composed. On the other hand, before a moderate external resistance, such as is afforded by a piece of platinum wire introduced into the circuit—as is the case in galvano-cautery operations—the potential electricity of the large cells becomes actual electricity; it has a door of escape, and it does escape, and in passing through the resisting platinum wire it is degraded into heat.

Drs. Kimball and Cutter reported two or three years ago some experiments in the treatment of solid uterine fibroids by electrolysis, with a large-cell quantity battery, and large and long knives as electrodes. Their idea in using a battery of this kind was, I suppose, that more electricity could be sent through the tumor from large and powerful cells than from small ones of the same kind. This fallacy is a very common one, but, as has just been stated, it is disproved theoretically by Ohm's law, which has no exception, and also by experiment and practical experience.

The method adopted by Drs. Kimball and Cutter has been criticised in articles in the *Boston Medical and Surgical Journal* by my friends, Drs. Webber, of Boston, and Hutchinson, of Providence. Dr. Webber suggested that only heating effects could be obtained, and there would be no electrolysis at all when a large cell was connected with a solid fibroid in the method of Drs. Kimball and Cutter. This criticism is doubly incorrect. The heat developed against such resistance as a solid fibroid would be imperceptible. In order to convert electricity into heat, there must be only a moderate resistance comparatively, and it must be proportioned to the tension of the battery, that is, to its power of overcoming resistance. If the resistance be so great that the electricity cannot pass to any extent, very little heat is developed in the circuit. If the resistance is only moderate and not sufficient to prevent the passage of the electricity, as in platinum, which is a poor conductor compared with copper, but a good conductor compared with the body, then the

\* In regard to the comparative conductivity of the human body and water, it may be stated that the warm saline fluids of the body as such, by themselves, conduct better than pure warm water outside of the body; but the body as constituted with solids and fluids is a much poorer conductor than warm water, and, indeed, conducts mainly through its saline fluids. The fluid contents of cystic tumors would probably conduct better than pure warm water.

electricity is developed, but is degraded into heat as it passes through.

In using a single large cell in operations with needles on solid fibroids, we do not get any heat, or only an amount that cannot be felt or easily measured; at any rate, no more heat than would be obtained under the same circumstances from a small cell.\* Precisely so with the electrolytic action. A large cell, no matter how large, will send but a trifle more of electricity through a solid fibroid than a small cell; it has, therefore, no practical advantage in operations of that kind. It would send absolutely no more electricity through a solid tumor than a small cell, except for the fact that its internal resistance—that is, the resistance in the battery—is less. In the cases of Drs. Kimball and Cutter, therefore, no perceptible heating effects were produced, and scarcely any more electrolytic action than would have been obtained from a small cell. If any injurious or fatal effects have come from that procedure, they were due probably to the size of the knives that were employed as conductors, although it is conceivable that the operation may have been too protracted, considering that both poles were inside of the tumor, a method which is not generally advisable in cases of that kind.

A battery composed of a small number of cells of moderate size is, therefore, the one required in the electrolytic treatment of solid uterine fibroid, fibrocystic, and also ovarian tumors. I have already stated that the actual decomposition of tissue—the electrolysis—is really the least important fact in the *rationale* of the so-called electrolytic treatment of this class of tumors; that the great thing is the indirect modification of nutrition through the nerves. Accordingly, it is probable that a battery, in which the chemical action goes on very slowly and feebly—as in the Daniell cell and in its modifications, for example—and which would afford the stimulating action of the electricity with but slight electrolysis, would have some advantages. The cabinet battery which I described three years ago is furnished with cells of this kind—the Siemens-Halske modification of Daniell's—and it produces but slight electrolysis even where it causes a decided sensation. The suggestion is worth consideration, and it is certainly in the interests of caution that it be carried out in those cases where there is likelihood that harm may come from electrolysis.

Tumors of the class under consideration may be treated with the negative pole only, or the positive pole only, or with both poles. There is greater safety when only one pole is used, and of the two the positive is least likely to do harm, from the fact that the oxygen and acids which go to that pole make less disturbance than the hydrogen and alkalis that go to the negative pole. In many cases, however, the negative pole is preferable, and particularly when it is desired to produce a vigorous chemical action. In regard to the choice of poles much will depend on the size and locality of the tumor. Not only the chemical, but also the irritating or stimulant effects of the negative pole are more pronounced than those of the positive pole, and this fact is to be considered.

\* Dr. W. F. Hutchinson has published some experiments verifying these deductions in a recent issue of the *Boston Medical and Surgical Journal*.

For a more detailed explanation of this somewhat difficult but very important subject—the application of Ohm's law to electro-therapeutics—I may refer to Chapter 7 of *Electro-Physics*, in Beard and Rockwell's *Electricity*, second edition. The conclusions from that law which I desire to emphasize just here are that Drs. Kimball and Cutter, in their experiments with a quantity battery, did get electrolysis as they claimed, but only a trifle more than they would have obtained from a single small cell; and secondly, that they did not get any important thermic or heating effects, as has been claimed by others.

In regard to the length of the operation much depends on the strength of the current used. A very mild current will be borne much longer than a very strong current—in case no anesthetics are used; and if the patient be anesthetized will be less likely to do subsequent harm. In the majority of cases it is desirable to avoid suppuration, if possible; hence it is well to do too little rather than too much; to repeat the operation many times rather than overdo the treatment the first sitting.

A very important practical consideration—and one that has not been recognized, or, at least, not insisted on hitherto—is that the suppurating point, after electrolytic operations, varies greatly in different individuals, and in the same individual at different times. This fact cannot perhaps be mathematically proved by rigid comparison, but it is a general judgment that I form from observation of the behavior of cases. With some persons a very long electrolytic operation is followed only by slight local inflammation, that soon passes away, and is attended with little or no pain; with other persons, in certain depressed states of the system, suppuration may appear speedily after mild electrolysis. I have observed this difference in all the varieties of tumors, as well as in cystics and fibroids.\*

The moral is that, in those cases where suppuration is not desired, it is well to be on the safe side, and use mild currents and short applications, as we cannot always tell beforehand in any case whether the suppurating point will or will not be easily reached.

Insulation of the needles is not indispensable, even in operations on ovarian cysts and uterine fibroids; for the very slight inflammation excited by the action of the needles when mild currents are used and the operations are short, does not tend to diffuse itself like inflammation excited by various other causes, but restricts itself usually to the track of the needle. This appears to be the case even in the peritoneum. It is better, however, and safer, to have the needles insulated when they are to pass through the peritoneum, although there is some practical difficulty in insulating needles thoroughly without making them too large, or hard to slip in. I have operated with a large number of needles through the abdominal walls without producing any evil results that could be traced to the action of the electricity on the peritoneum, or to the irritation of the needles themselves.

The fatal results that have followed electrolytic operations on fibroids of the uterus may be explained in various ways. The currents have been too strong and have been used too long; too large needles or other conductors have been used, consequently suppuration has been excited. There has been some blind experimenting in this direction, which need not be repeated.

In some cases fibroids of the uterus can be treated through the vagina by means of very long needles, and

\* In illustration of this difference in the suppurating point after electrolysis I may refer to two or three cases:

I treated with both poles and quite a strong current a large ganglion on the wrist of a lad of about twelve years; considerable inflammation followed, as in that case I desired, but it did not extend along the sinus, and did not lead to suppuration, and the result was excellent.

On the other hand, in a case of a large cystic tumor on the head of a boy in the Presbyterian Hospital, electrolysis in both operations caused suppuration and unpleasant symptoms; a cure, however, was effected, as has been reported to this Society by Dr. Post. With still greater caution suppuration might have been avoided.

Quite recently I have treated a case of carcinoma of the neck in a patient of Dr. Hamilton, an old gentleman, whose relief of the severe pain was quickly gained by external galvanization, but desiring to reduce the size of the tumor, and prevent, if possible, its pressing on the throat so as to make deglutition impossible, I used needles; suppuration followed at once; the tumor was very much reduced in size; the throat was relieved, although, as was expected, he died from exhaustion. I have used ten times as much electrolysis in cancers without producing suppuration.

when this method of introduction is used suppuration is not necessarily to be feared, since a free outlet is afforded. In one case of uterine fibroid that I treated in this way, using a single long needle, connected with the negative pole through the vagina, not a little suppuration occurred, but no evil symptoms accompanied, but on the contrary great relief of the numbness, neuralgia, and other results of the tumor, and this relief did not come until the suppuration appeared.

The results of the electrolytic treatment of cystic and fibroid tumors vary with the size and nature of the growth, with the locality, and with the constitution and condition of the patient.

Benign cystics that are directly accessible can in almost all cases be permanently cured or reduced to a harmless minimum by electrolysis. Malignant cystics can sometimes be treated successfully by electrolysis of the base, and sometimes can be arrested by ordinary electrolysis.

Ovarian tumors, if treated cautiously and judiciously, with proper apparatus, so as not to excite suppuration or severe inflammation, offer, to say the least, an encouraging field for experiment; and the probability is that a certain proportion of cases, if taken before too great size is attained, will be radically cured in this way. Generally, however, these cases are not seen early. The published experience—favorable and unfavorable—of Fieber, Semeleder, and Ulzmann in this department is worthy of note. Dr. Hesse, of Brooklyn, has recently reported a case of ovarian tumor satisfactorily treated by electrolysis.\*

There may have been failures in the past, where in the future there will be partial or complete successes. There need be ordinarily no danger in electrolyzing these cases, provided the conditions and cautions here suggested are not forgotten. In this as in other applications of electricity, the greatest mistakes are made in overdoing the treatment, in attempting to concentrate everything in a short time, and in treating all cases alike. Next to cystics, fibro-cystics probably have the best prognosis.

Solid fibroids of the uterus yield in some cases to electrolysis almost as well apparently as goitres; in other cases, just as with fibroids in other parts of the body, no reduction in size is obtained over what comes from actual destruction of tissue. In all, or nearly all, cases, judging from my own experience, and from the published reports of other observers, relief of accompanying symptoms, as neuralgia, numbness, and so forth, can be obtained, even when there is no important reduction in the size of the tumor.

The different varieties of tumors in regard to the comparative prognosis under electrical treatment may be arranged in the following order:

1. *Nævi*.—Including those raised above the skin, those beneath the skin, and the cutaneous *nævi*, or mother's marks, when not too large.

The electrolytic treatment of *nævi* is indeed one of the most satisfactory departments of surgery.

2. *Benign Cystics*.—Including "weeping sinews," hydrocele, and possibly also small ovarian tumors, as well as cystics in other parts of the body.

3. *Goitres*.—Some varieties yield far more speedily and more satisfactorily than others, including exophthalmic goitre.

\* *Am. Jour. of Obstetrics*, Jan., 1877. The same Journal also contains a report by Dr. Thomas of the statistics given him by Drs. Kimball and Cutter of the results of their experiments in the treatment of uterine fibroids. Dr. Hutchinson informs me that he has recently treated satisfactorily a case of uterine fibroid by electrolysis, using a mild current and the positive pole. Dr. Livingston, of this city, tells me that he has treated, during the past two years, an intra-mural uterine fibroid by *external* galvanization alone, and very decided softening has resulted.

4. *Epithelioma* of the face, particularly when treated by the method of electrolysis of the base.

5. *Fibroids*.—Including fibroids of the uterus.

6. *Fatty Tumors*.—These, when not too large, yield slowly, because fat is a poor conductor, and electrolyzes with difficulty; but, when not too large, they can be radically cured.

7. *Carcinoma*.—When we consider the rapid relief of pain obtained in even the worst cases of cancer, and the fact that in some cases the growth is arrested, it may be queried whether this variety should not come earlier in the list.

8. *Glandular Tumors*.—This variety is placed at the foot of the list, because of the difficulty in making enlarged glands diminish in size without suppuration.

In conclusion, it may be added that the one general fact that this discussion enforces is the necessity of grounding our electro-therapeutics on electro-physics. Electro-physics—that is, electricity in its physical relations, including the theory of the nature of the force, the methods of generating it, and the laws that control its phenomena—is far more important, practically, for one who uses electricity in medicine or surgery, and particularly in surgery, than electro-physiology. If either are to be neglected, let it be the latter. It was a want of knowledge of electro-physics that kept back electro-therapeutics for one hundred years subsequent to the discovery of the Leyden jar; it is a want of a diffusion of the right knowledge on this subject, and the erroneous teaching of colleges, schools, and text-books, that cause many of the failures and disappointments and inconsistency of results at the present day, as has been illustrated in the history of the special topic here discussed. While here, as in all other therapeutics, much for the present must be empirical, yet in the future, as in the past, the progress of scientific electro-therapeutics, surgical and medical, will be in proportion to the advance and popularization of just views in electro-physics.

## INSTRUMENTS OF GLASS FOR WASHING OUT THE PUERPERAL UTERUS.

By W. M. CHAMBERLAIN, M.D.

WITH REMARKS UPON THE LOCAL ANTISEPTIC TREATMENT OF PUERPERAL DISEASES, BY DR. H. FRITSCH, OF HALLE.

THE use of glass as material for surgical implements is desirable, on account of the certainty and facility with which it may be cleaned, the smoothness of its surface, and the fact that iodine, nitric and chromic acid, etc., etc., which destroy metals and vulcanite, are harmless to this substance.

It does not wear out, it does not corrode; it is always the same, incapable of injury, except by breaking.

Recent processes of annealing have removed in good measure this objection. The method of de la Bastic is only a new application of old ideas. The boiling oil in which he plunges the glass while red-hot does not confer any qualities upon it.

It is simply a non-conductor, capable of absorbing a great deal of heat, and parting with it very slowly. Consequently the glass immersed cools very slowly and equably throughout. Thus treated, it retains a condition intermediate between the perfect plasticity of the molten mass and the perfect brittleness of the same when suddenly cooled in air.

Of material rendered tough by a similar process I

have made canulæ, which will, I think, be found serviceable.

They are figured in the annexed wood-cuts.

No. 1 is a female catheter, 10 of the American scale, designed for use in the office, and especially for women after delivery, when, by reason of septic lochia or diphtheritic lacerations of the vagina, any other instrument would become contaminated, and so a source of infection upon further use.

Nos. 2 and 3 (only one size shown in cut), are simple canulæ, through the calibre of which a slender whale-bone stilet, wrapped at one end with cotton, may convey to the interior of the uterus iodine, nitric acid, or any other escharotic, without the risk of its being applied in transit to the cervical rugæ.

One reason why these applications have not answered expectations is doubtless that the caustic has been neutralized by the alkaline mucus of the cervix, or expended upon a surface which it was not desired to affect.

To obviate this, Atthill and others have been accustomed to introduce three, four, or five laminaria tents, and thus procure an excessive dilatation of the cervix, which is always undesirable and sometimes mischievous.

The smaller of these canulæ may be passed through many relaxed cervixes. Either of them will readily follow the medium sizes of Peaslee's or Kammen's or Hanks' dilators, a single laminaria tent, or a single and moderate use of Ellinger's or Miller's expanding instruments.

I therefore regard them as more than a convenience, as an absolute saving of an unnecessary and tedious process.

No. 4 is a stout tube fifteen inches in length, and five-eighths of an inch in diameter. The curve has

been experimentally adapted for readily entering the puerperal uterus. The distal end is closed and rounded like the smaller end of an egg (paraboloid). Beginning half an inch from the closed end on the posterior surface, and following a spiral line around it, are four holes, one inch apart, on the various faces of the instrument. These holes are made when the glass is hot; the edges are, therefore, glazed, and the strength of the instrument is not impaired, as it would be by drilling. They are also a little countersunk, to make sure that they shall not be occluded by applying against the shaggy endometrium. The holes are so arranged that a current cannot be thrown upon the orifices of the Fallopian tubes.

The straight end of the tube is reduced in size to connect with the rubber tube of a syphon irrigator or fountain syringe.

The purpose is to wash out the puerperal uterus, as follows: The patient lies upon her back, with her knees drawn up—beneath her hips is placed a pillow covered with a rubber-cloth continuous nearly or quite to the foot of the bed; a channel may be made in this to lead the water into a pail, as the amount should be more than any bed-pan can contain. The operator, standing erect by the side of the bed, passes the curved end of the connected tube into the vagina, three or four inches, or until a slight resistance tells him that the closed end applies upon the os uteri. The stopcock is opened and the carbolized water, a quart or more, is allowed to flow with a regulated pressure into the vagina until all its surface has been thoroughly washed. This may be aided by a slight rolling motion of the instrument. The straight end is then lowered nearly to the level of the bed, and the beak, *without the introduction of a guiding finger*, slides easily, or after a little manipulation, up to the fundus, and one or two quarts of the disinfecting fluid is passed in and out. If there be any doubt about the ready escape, the flaccid anterior lip may be raised by a lifting motion upon the instrument.

The object is thus accomplished with the least possible irritation to the patient, and with the least expense of time and trouble to the operator, *who is further freed from direct contact with any septic fluid.*

This washing out of the uterus, when at all required, is certainly a matter of first-rate importance.

I find the subject so well treated in a paper by Fritsch, of Halle, that I subjoin a translation of a portion of the same. It forms No. 107 of Volkmann's *Sammlung klinischen Vorträge*, and my attention was called to it by Dr. A. Mayer, of this city. It bears date, Leipzig, Dec., 1876. The translation is sometimes continuous, sometimes detached sentences are omitted. It is to be understood that the author writes in view of those epidemics of puerperal fever (so called), which occur so frequently in the maternity hospitals on the Continent.

... The preparation of the woman about to be confined consists in that she always goes to a Sitz-bath, to be ordered when the labor-pains begin.

"In the Sitz-bath let the vulva and perineum be thoroughly cleansed with soap. Then let the vagina be irrigated with a solution of carbolic acid, and with the remnant of the solution a second cleansing of the vulva be made. . . . Fehling, in Leipzig, made the experiment of delivering the pregnant woman under spray, but has abandoned it, since a connection between the use of spray and after bleeding was clear.

"Despite this inconvenience in a lying-in hospital where an endemic existed, I would never make an obstetric operation without the spray.

"If the birth be delayed and perhaps operative procedures undertaken, repetition of the vaginal irrigation is important, particularly before any of the greater operations should it be done.

"I have considered whether the somewhat astringent effect of the carbolic solution might not render the vagina rigid or dry. On this account I have directed that an injection of carbolized oil should follow the irrigation. But this is not necessary. The passage remains soft and succulent, and the customary oiling of the finger causes us to recognize no difference before and after irrigation.

"Passing now to the period after birth, we may next consider how nature provides for the escape of the lochia. The conditions for the delivery of this fluid are not altogether favorable. In the recumbent position, especially when the hips have made a place for themselves in the cushions or mattress somewhat below the general level, the deepest portion of the pelvic cavity is below the level of the posterior vaginal commisure. Even though a tear of the fourchette should favor escape of the lochia, yet the collapsed condition of the rectum causes a deeper cavity. Its fluid must then attain a certain level before it can flow out. A greater or lesser quantity will remain behind, enough to decompose all following discharges. And, when it reaches this needed level, the fluid will not always escape.

"Inspection will show this. . . . If you syringe the vagina with a female catheter, you will notice that the relaxed and cohering labia do not allow the fluid to pass out below, but it issues above, where the conditions are more favorable, on account of the close apposition of the soft parts from the vulva to the knees. It is often quite a while before the water presses apart the agglutinated walls. For example, in the earlier days of confinement, when there are still blood coagula in the vagina, the flow of injected water often ceases entirely; by and by the vulva separates; the coagulum, and after it a great quantity of water flows out.

"Still more unfavorable are the conditions when edema of the vulva already exists. Upon touching, during irrigation, we constantly find that the cervix projects free into the cavity, and that the vault of the vagina is not in immediate apposition with it. If the patient raises herself after the injection flow has ceased, there will pour out anew a large quantity of residual injection fluid. In fever cases this large cavity is filled with infectious material. As stands a plant in the ground, so with all its lacerations stands the cervix in a pool of stagnating secretions.

"If now we ask what practical inference may be drawn from these several theoretic conclusions, it is this: that in every case the lochia must be evacuated.

"Even in entirely normal cases, this should be done, if we would remove the possibility of a subsequent invasion of disease. And a selection of cases is impossible, since the resort to rational treatment may surely come too late.

"Half-way measures, such as the application of disinfecting compresses, powdering, washing, or cauterizing abrasions, are proper only when the pelvis has been evacuated. Provided this is done from the first, no ulcerations will form, and wounds will heal without special treatment.

"The value of a clyster in confinement is generally admitted, and washing out the vagina is no greater undertaking. I direct that, at the morning and evening visit of the midwife, the vagina shall be washed out, and the vulva cleansed. If I do not know the midwife, the first injections must be made under my

own observation. . . . For injections I employ carbolic acid. Surgeons also have observed that salicylic acid is of little value. Even cotton tampons saturated with salicylic acid soon become offensive, and after injections of it the bad smell quickly returns. The strength of the solution should be two per cent.; but stronger are not excluded. The temperature should be 25° R. (= to 89° F.); in the later periods a lower temperature, at discretion, may be employed.

"The irrigator (equal to our fountain syringe or syphon-tube) is the proper instrument to be used when the cavity of the uterus is to be cleansed. It should contain at least a quart (litre). I have often observed that, in the early cleansing, it is only with the third litre that the fluid begins to come away clear. It is needful then to continue the irrigation so long. With the remnant of the solution is the vulva and its hair, from mons to anus, to be thoroughly washed. . . . If any operation has been made, repeated washings, particularly when the operation has been on account of a dead child, should be made.

"Irrigation is of special importance when liquor ferri has been injected. . . . Here the washing out, the removal of the stringy coagula, is an integral part of the treatment of the metrorrhagia. In such cases not to excite a fresh bleeding, I have syringed the uterus for the first time, thirty-six hours after delivery, or after the stoppage of the bleeding. . . . As actively should we proceed when we are called to a lying-in woman who has suffered from fever for one or more days. Then usually the uterus is holding back a certain amount of ichor. . . . In such cases there appears, on account of the infiltrated condition of the uterine parenchyma, a peculiar relaxation of the whole organ. We find by autopsy the uterus often so oedematous, that the rectum has left an impression of itself in the surface of the womb, and by irrigation we see that the stream of water directly dilates the uterus. . . . The simple inference follows that the lochia or the ichor must be evacuated. The indications are the same as with any other dead secretion.

"The treatment of a puerperal affection without cleansing the vagina is something entirely irrational, an obsolete nonsense. We think it inconceivable that one should try to heal a thigh lacerated by gunshot wound and full of ichor by internal medication; yet have they tried to cure puerperal fever by inward medicine, as alcohol, quinine, veratrum, ammonia. Here the prime, the unavoidable indication is the cleansing of the localities from which resorption takes place.

"As the surgeon cleanses every wound, and has for a hundred years considered this the leading feature of his treatment, so must the obstetrician free the uterus and vagina from corrupted lochia.

"It would be a great step in advance if we came to consider the cavity of the uterus as an ichorous abscess-hole, and treat it as the surgeon treats similar deep abscesses."

This may seem strong language, but some experience in puerperal fever satisfies me that there is important truth in it. The remainder of the article of which the above is a portion will be found interesting.

68 WEST 40th STREET, March 3, 1877.

MEDICAL LEGISLATORS.—There are seven medical men in the State Assembly this year: Dr. Thos. J. King, of Cattaraugus; Drs. DeWitt Webb and Thos. Hammond, of Dutchess; Dr. M. Billington, of Madison; Dr. Isaac Hayes, of New York; Dr. David McFalls, of St. Lawrence; and Dr. Wm. Gulick, of Schuyler.

## A NEW METHOD OF OBTAINING EXTENSION AND COUNTER-EXTENSION IN FRACTURES OF THE FEMUR.

By J. H. CHURCHILL, M.D.,

CROSS RIVER, WESTCHESTER CO., N. Y.

The imperfect union which so often occurs in intracapsular fracture of the neck of the femur is attributed more especially to absence of periosteum within the capsule.

The impossibility of obtaining provisional callus is of course a serious hindrance; but a more serious obstacle to the formation of definitive callus is the almost inevitable rocking of the fragments in consequence of the tendency of the thigh to rotate about its longer axis. The fact that the separated head receives no nourishment except through the round ligament is not of so much importance, as it would seem that the same circulatory apparatus that was sufficient for the formation of the bone in the first place, and for its nutrition afterwards, would be sufficient for its repair.

The difficulties attendant upon the use of the long splint are too well known to need comment.

Having to treat recently a case of fracture of the neck of the femur in a patient sixty years of age and in thin flesh, I devised the following methods of getting counter-extension: A strip of freshly prepared adhesive plaster six inches wide was fitted about the pelvis, the ends lapping in front. Two strips of plaster, one and a quarter inches wide, were applied to the perineum and carried up over the pelvis, so as to lap on the wide plaster in front and behind. A muslin roller somewhat wider than the plaster was then passed about the pelvis, the ends being sewed together in front. Four loops had been strongly secured to the wide adhesive plaster so as to come over the hip on the injured side; these were brought through slits in the roller bandage and through fenestra in the long splint. A stout piece of muslin was now passed through these loops and tied so as to secure the splint firmly to the plaster. Extension was made in the usual way, and the splint, properly padded, was bandaged to the leg and thigh.

Before applying the splint in this manner, I had, on the day of the accident, applied it in the usual way, and on removing it the sixth day for the purpose of reapplying, the perineum appeared much excoriated and there was an ulcer over the sacrum. These rapidly healed under the plasters, and when the apparatus was removed, just six weeks from that day there was no abrasion to be found. The patient has a perfect joint, and not sufficient shortening to be appreciable to herself in walking. The success seems sufficient to warrant the presentation of the appliance to the profession for further trial.

For extension I have devised a method which is useful in some cases. The screw is removed from the lower end of a long splint, and the foot-piece attached to a strap which passes over a roller in the end of the splint and up the outside. It is attached to a strong elastic by means of a buckle, and the elastic is attached to the upper end of the splint. By means of the buckle the elastic may be stretched more or less, so that any degree of extending force which may be required can be obtained.

DR. J. MARION SIMS has been elected honorary member of the Obstetrical Society of Dublin.

## Reports of Hospitals.

### BELLEVUE HOSPITAL.

#### NOTES OF PRACTICE AND PECULIARITIES IN TREATMENT.

##### TREATMENT OF CONSTIPATION ASSOCIATED WITH CHLOROSIS.

It was believed to be of nervous origin, and due to paralysis of the intestines; there was also spasmodic constriction of the intestinal tube. The result was complete relaxation and dilatation of the tube at one part, and stricture at another. It was maintained that there was associated with this condition either a deficiency, total suspension, or perversion of the alimentary secretions from the liver down; hence the pale color of the stools and the white viscid mucus that commonly coated the mucous membrane. The constipation being a nervous disease, and due to reflex irritation of the plexuses of nerves and their ganglia which have to do with the innervation of the circulation, the following plan of treatment was recommended:

First, operate upon the peripheral extremities of the nerves involved, by means of external application. It was a well-known fact that when the feet and hands were plunged into water, contraction of the ovarian plexus of nerves was produced; hence one of the most natural methods for bringing about increased flow of blood to the uterus was to avail ourselves of the stimulation produced by dry heat applied to the feet and hands. It was believed that many cases of chlorosis could be mainly relieved by the application of dry heat to the feet, and cases were cited in which electricity, applied to the cervix and interior of the uterus, had failed, but heating the feet upon the stove for three hours every day had restored menstruation. Any of the irritant stimulants, when used for the special purpose of increasing arterial circulation, had precisely the same action as dry heat; that is, they stimulated the heart, hence increased the arterial current. In addition to the dry heat, wrapping the feet and arms in cloths wet in a solution of capsicum, and applying the same over the bowels, would be found to be of great assistance in overcoming the constipation.

It was recommended not to resort to cathartics until the measures just mentioned had been employed for some time. Of cathartics, aloe and rhubarb were said to be the most serviceable. The form most convenient for their administration was the compound rhubarb pill, and of those three might be given at night twice a week, or even every night, until the bowels had been rendered soluble. Iron should never be relied upon unless used in conjunction with these two remedies. When the bowels had been rendered soluble, iron might be used; but all its preparations were precluded, with a *single exception*. The very best results were obtained by combining sulphate of iron with carbonate of potassa and nux vomica, as in the following prescription:

℞. Potassæ bicarb. . . . . ʒss. to ʒij.  
Ferri sulph. . . . . gr. x.  
Ex. nucis vom. . . . . gr. x.

M. et div. in pil. No. xx.

S.—One to be taken after each meal.

In addition, it was desirable to have a pill which could be administered subsequently, whenever the bowels became confined. To restore innervation and rhythm to the muscular coat of the intestine were the indications to be met by such a pill. For that pur-

pose there were two agents which could be employed—namely, belladonna and nuxvomica. For the purpose of restoring innervation to involuntary muscular fibre, belladonna was regarded as the most serviceable. If the two remedies were combined with small doses of a real laxative or cathartic, it would be found that such small doses would produce free catharsis, whereas double the quantity would be required to produce the same effect if administered alone.

For the constipation under the circumstances alluded to, the following prescription was written:

R. Ext. belladonnæ..... gr. v.  
Ext. nucis vom ..... gr. x.  
Ext. colocynth. co..... ʒi.

M. et div. in pil. No. xx.

S.—One to be taken at bedtime.

If the colocynth griped, the griping could be prevented by the addition of ʒij of the bicarbonate of soda, and then dividing the mass into 40 pills, of which two instead of one should be taken.

Electricity was regarded as a valuable agent in the treatment of chlorosis, simply because it operated as a stimulant to the circulation, the same as dry heat. It was desirable to apply it to parts associated with the uterine circulation; and that could be conveniently done by placing one pole of the battery upon the soles of the feet, and the other over the sacrum. The proper time for such application was immediately after breakfast, because the electricity also acted upon the intestines, and that being the normal time for an evacuation from the bowels, it might materially assist in overcoming the constipation.

PLEURISY, WITH EFFUSION—HYDRO-PERITONEUM—  
OEDEMA OF THE FEET—INDICATIONS FOR REMOVAL  
OF THE FLUID FROM THE PLEURAL CAVITY—IN-  
STRUMENT WITH WHICH IT WAS REMOVED.

The patient was a Polish woman, who was deaf and entirely unacquainted with the English, and had only a very slight knowledge of the German language. Nothing was known of her history. There was considerable fluid in the abdominal cavity, but nothing sufficient to render an operation for its removal immediately necessary. There was a moderate amount of oedema of the feet, but an examination of the urine gave negative results; and there was no evidence of chronic cardiac disease. Nothing was known of the habits of the patient, but the hydro-peritoneum involved a strong presumption regarding the use of alcoholic stimulants. In addition, the woman had a considerable quantity of liquid in the left pleural cavity alone, and it was not, therefore, hydrothorax. When she made any exertion her respiration became considerably embarrassed. The apex beat could not be found, but the cardiac sounds led to the conclusion that the heart was crowded over to the right side, so that the apex was under the sternum. When liquid in the pleural cavity gave embarrassment to the respiration, and was not promptly absorbed by the employment of measures having reference to the promotion of absorption, or the patient was found too feeble to bear the presence of the fluid well, there should be no delay, said the visiting physician, in effecting its removal by means of an operation which has been made so trivial as to involve no liability to danger, and yet was capable of accomplishing in a few minutes, what, under the most favorable circumstances, by the use of remedies, would require considerable time.

An instrument devised by Prof. Flint some fourteen years ago, called "Flint's Aspirator," was employed, and ʒxxxii. of fluid removed from the pleural cavity.

A description of the instrument can be found in the *RECORD* for Dec. 2, 1876, where it is claimed as a new invention by Dr. Gritti, of Milan, and published in the *Lancet* for November 4.

## Progress of Medical Science.

SALICYLIC ACID AND ITS COMPOUNDS COMPARED WITH OTHER ANTISEPTICS.—According to the results of some comparative experiments which Mr. Lapper has done, the value of salicylic acid in arresting putrefaction is not so high as some other substances which are in use for the same purpose. He obtained some fresh bullock's blood, had it defibrinated, and then mixed it with a  $\frac{1}{1000}$  part of its weight of various so-called preservative substances; one series of experiments was then conducted at a temperature of 100° F., that of living blood, and the other at the ordinary temperature at which experiments are usually made. Though the amount of the antiseptic employed was small, it was very much larger than is administered in disease, and Mr. Lapper holds the opinion that the usual quantity prescribed is very far from being sufficient to act with special antiseptic force upon such a large mass as the living blood. Salicylic acid in the proportion used was found to have but slight effect in preventing putrefaction. The synthetical acid, or that obtained by Kolbe's process, was slightly superior to the acid from oil of wintergreen. The salicylate of potassium seemed to prevent putrefaction to the same extent as the acid itself. The zinc salt had an equal potency at blood heat, but a greater at the ordinary temperature. With the zinc sulpho-salicylate it was the reverse, its efficacy being greater at a higher than at a lower temperature. Carbolic acid at the ordinary temperature stood pre-eminent, while at the higher it was inferior in arresting putrefaction to both sulpho-carbolate of zinc and sulphate of quinia. The bisulphite of sodium seemed to hasten putrefaction at 100 F., while at the ordinary temperature it had no effect whatever. Benzoic acid at 100 F. had the same potency as carbolic acid, but at the ordinary temperature it was inferior.—*Dublin Journ. of Med. Sci.*, April, 1876.

CURE OF ANEURISM BY COMPLETE TEMPORARY PRESSURE.—Another case has been reported in which elastic pressure has been successful in the treatment of aneurism. A man, thirty-nine years of age, the subject of syphilis, was taken into the Nottingham Hospital on the 1st of November last, suffering from a femoral aneurism of six months' duration. For the first few days, rest in bed was the only treatment adopted. Then a Carte's compressor was applied to the external iliac and common femoral arteries, but no benefit was observed in either case. Then from November 7th to December 4th pressure with a shot-bag was more or less constantly used, and the diet was regulated by Mr. Tufnell's rules. Still no improvement was seen, and finally the elastic bandage was tried, the foot, leg, and thigh being strongly compressed, while a stout rubber tourniquet was fixed round the limb above the bandage. This was done at 11:15 A.M., Dec. 31st. At 1:30 P.M. the tourniquet was removed and a shot-bag was placed over the vessel, but the bandage was allowed to remain in position. At 2:30 P.M., when the bandage was removed, the tumor was found to be firm, and the pulsation had ceased, except at the upper part. As a precautionary measure the application of the shot-bag was

continued. At 12:30 P.M. of the next day all pulsation had ceased, though it returned again in the evening, and continued feebly until January 4th. On January 5th pressure over the artery was discontinued, and the case was practically cured. It is thought that in this case the mode of cure was by the deposition of laminated fibrine within the sac, for the return of the pulsation, and its continuance for several days, would prove that the main vessel leading into the sac had not been completely plugged. In the cases of popliteal aneurism which have been reported cured by Esmarch's method, it was said that the pulsation did not return after its arrest at first, and in Dr. Reid's case dissection showed that the cure had taken place by plugging of the afferent vessel, and organization of the clot. It is therefore thought that the method of cure in elastic pressure may be in two ways, viz., by the gradual deposition of laminated fibrine, or by plugging of the afferent vessel.

While the compression of the main artery only does not control the collateral and anastomotic circulation, but allows a certain quantity of slowly-moving blood to pass through the sac, the total compression by means of the elastic bandage allows not only the coagulation of the blood left within the sac, but also the formation of a firm clot within the artery leading into the sac, afterwards to be connected with the walls of the vessel by organization.—*Lancet*, Feb. 3, 1877.

**RUPTURE OF THE SPLEEN, WITH RECOVERY.**—According to the *St. Petersburger Med. Zeitsch.*, a physician, thirty-three years of age, after an attack of typhus fever, and seventeen days of convalescence, had four short but sharp exacerbations of fever, in which the spleen became larger than at any time during his illness. After a severe fit of vomiting, symptoms of rupture of the spleen, with internal hemorrhage, set in; the pain in the epigastrium was intense and paroxysmal; an increased area of dulness was manifested about the enlarged spleen, and there was collapse. The symptoms of extending dulness and collapse increased, the temperature sank, and there was cyanosis and suppression of urine. Bladders of ice were applied to the abdomen, and a grain of opium was given every three hours, and finally subcutaneous injections of camphor were tried and enemata of port wine. On the following day there were no symptoms of peritonitis, and at length there was absorption of the extravasation and general improvement, terminating in recovery. The seriousness of the accident may be judged from the fact that of twenty-two similar cases, conducted by Kerner, all died.—*Berl. Klin. Woch.*, 4, 1877.

**ABDOMINAL ANEURISM TREATED BY ACONITE AND REST—RECOVERY.**—Dr. Grimshaw reports a case in which a permanent cure resulted under Tufnell's method, in combination with aconite. The patient was admitted into Stevens Hospital, Dublin, April 7, 1875. A large tumor was found to occupy the upper part of the abdomen, in the epigastric region. It reached nearly as far down as the umbilicus, was lobular in form, tolerably firm, and had violent expansile vibrations. A loud bellows murmur was heard over the tumor and along both sides of the spine behind. The patient also complained of much pain in the tumor, back, and limbs, and the feet were occasionally swollen. A diagnosis of aneurism, either of the aorta or some of its branches, was made. As it seemed clear that the patient would not submit to the rigid plan laid down by Mr. Tufnell, some modifications of it were made. Rest in the recumbent position as enjoined, but the patient was allowed to turn on his side, and move about to a considerable extent.

He was kept on low diet, consisting of bread and tea, beef-tea and soup, but no stimulants were allowed. Dr. Grimshaw having also found that aconite proved to be beneficial in two cases of thoracic aneurism, determined to employ it in this case, believing that in this way the patient's life might be prolonged, though a cure was hardly to be expected. Accordingly, while following the method already mentioned, the tincture of aconite in five-minim doses was administered every three hours. On the day following, the pulse had diminished to about 50 per minute, though the patient did not admit there was any diminution in the local symptoms. On the following day, however, he felt the beating only once, but complained of burning in his mouth, and tingling in his limbs. The pulse was slow and weak, and the limbs showed a tendency to become cold. The pulsations had clearly lessened. At the end of a week the symptoms of aconite poisoning became so marked that the amount was reduced one-half, at which daily quantity it was given for three months, the plan being to diminish the drug only when there was tingling in the extremities. In July a considerable improvement had taken place in the tumor, but the patient's general health had failed, so that an addition of meat and strabout was made to his diet. The aconite was diminished, and finally abandoned on August 24th, and Parrish's syrup was given instead. On November 7th the tumor had very much decreased in size, and the murmur was inaudible, but there was some pulsation. On November 14th the pulsation had ceased, and on December 8th he left the hospital, having been there altogether two hundred and forty-four days. The patient is now in the possession of good health, though he is not so active upon his legs as before his illness. Dr. Grimshaw believes that in a certain number of cases patients will not submit to Tufnell's treatment, and in such he would suggest aconite. At any rate, the two methods may advantageously be used in combination.—*Dublin Journ. of Med. Sci.*, April, 1876.

**ROUGH AND READY LITHOTOMY.**—A paper on "Indian Surgical Instruments" is published in the *Indian Medical Gazette* by Dr. R. Temple Wright, from which we glean the following account of the manner in which the native doctor cuts for stone. The patient is first drugged with cannabis indica (largely used in the country as an intoxicating agent, both as a sweet-meat and mixed with tobacco), and the bowels are cleared out, after which he is tied up in the usual lithotomy position. The practitioner then, without using any sort of staff, passes the index and middle fingers of his left hand into the rectum, while with his right hand he presses on the supra-pubic region, so as to bring the bladder and its contents as far as possible within the reach of the left hand. He then pushes the stone towards the perineum with the fingers which are in the rectum, and then with "an old razor" makes a free incision *transversely* across the perineum, "knowing and caring nothing about the anatomy of the region," but cutting deep enough to reach the stone, which he hopes will come out with a jerk when he has cut far enough. If it does not jump out, he either pulls it out with his fingers or forceps, or extracts it with a goat's horn or a rough scoop. Undue hemorrhage, singularly enough said to be unusual, is stopped by the application of ashes and earth. We are reminded by the foregoing of a famous Italian quack, who was remarkably successful in performing lithotomy until an English surgeon taught him the anatomy of the region he hacked, after which no consideration or bribe would induce him to adventure on another operation.—*Lancet*.

# THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, March 17, 1877.

## CONCERNING MEDICAL DISCUSSIONS.

It may be difficult to believe, judging from the published reports of medical societies, that the discussions of papers and relations of cases are not what they should be. The truth is, however, that hardly one-half of what is said and done during the meetings of these bodies is ever heard of outside the walls of the meeting halls. We imagine that this is the case everywhere, and on all occasions, whenever a promiscuous body of men come together to discuss, without order or method, any and every subject which may be presented. When we view the results in the mere light of accidents of circumstance, there is always a wide latitude for the charitable interpretation of a motive. But the great majority of irrelevant discussions do not come under this category. As a rule, irrelevant matter is brought before societies, less as a result of innocent misapprehension of the questions at issue, than a deliberate intention to say something at all hazards. We have too many gentlemen in this city who look upon the societies as advertising media for the sale of their intellectual wares, and who lose no opportunity for presenting them in as many different phases as may best suit their purposes. There are not a few who are present at every meeting, and whose conscientious regard of a personal duty compels them to make a few remarks upon every subject presented. Out of a mistaken courtesy the chairman allows them to talk, and out of self-sacrificing politeness the members suffer the infliction. We do not wish to deny these gentlemen the pleasure which they may derive from talking; indeed, the intensity of their enjoyment during the performance makes every listener realize that it is more blessed to give than to receive. If, perchance, as the result of this wandering loquacity we get a single new idea, or a pertinent suggestion, we forgive ourselves for the toleration. All this, however, takes time, is a severe tax on the vaso-motor system, and should be repressed. The chairman of

such a meeting has a heavy responsibility to discharge. His duty very plainly lies in the direction of at least a mitigation of the evil. If he cannot actually prevent the speaker from rising, he can keep him sufficiently to his text to cut him short, so that we can get at the raisin in his pudding without chewing too much of the introductory crust, or without learning how the oven was managed to cook the dish. Associated with irrelevant and windy discussion is the tedious detail of cases. The most unimportant matters are magnified beyond any calculation of ordinary discretion, as if it were necessary to fire a cannon every time a patient had a passage from his bowels. We are happy to say that these cases are exceptions to the rule, and that there are plenty of men in New York who never speak but to a purpose, who are always listened to with pleasure, and to whom the societies owe whatever of real usefulness they possess.

## PUERPERAL FEVER IN CHARITY HOSPITAL.

THE letter of Dr. Gillette, which appears in another column, calls our attention to the remarks we made recently in reference to the occurrence of puerperal fever in Charity Hospital. We take occasion to review his statements because it gives us an opportunity for proving that there is not so much difference between us as would at first appear. On the contrary, his remarks serve more as an endorsement of what we said than as a criticism. Our main object in calling attention to the subject was to point out the danger of treating puerperal women in large hospitals. We have no reason to doubt the accuracy of his statistics, or the conclusions founded upon them. In fact, the flattering exhibit of success in treatment narrows the question to the real influence of hospitalism as a genetic factor of puerperal fever. If we understand Dr. Gillette he freely admits the tenability of such a view. The mere assertion that the lying-in wards being in Charity Hospital is not detrimental to the service, in the sense that the same service at Bellevue was detrimental, is a question of difference of degree rather than one of kind. For the sake of the argument we may assume that Charity has every hygienic opportunity for stamping out puerperal fever, except that it has the misfortune of being a large hospital. In other words, if we could only do away with the hospital as such, there seemingly would be no possible chance of generating fever cases. But we do not feel ourselves bound to imagine that the doctor is an advocate for large hospitals for puerperal women. On the contrary, we believe that he is willing to confess that pavilions are better, and that the completion of the structures to which he refers will meet many if not all the requirements in the case. We do not quite agree with him that the construction of temporary pavilions is a Utopian idea, for nothing is Utopian which is possible, and, further, we fail to see the force of his argument that anything said or done in the way of reform in his

management—a reform which he tacitly admits legitimate—should have a hampering or discouraging reaction upon “Charity.” If it were not for the facts which he so generously places at our disposal, we might be inclined to suppose that he was begging a real point at issue by confounding the arrest of the disease with its prevention. We confess ourselves most concerned in the latter, and shall, in view of our duty, continue to criticise the policy of treating pueral women in general hospitals. If our correspondents would have us believe, by any statistics which he has given, that the management of Charity Hospital, in this regard, is absolutely faultless, we distinctly regret that we take issue with him; but if he is willing to admit the contrary we heartily sympathize with him in his efforts for reform. Whichever way the matter is viewed we have no reason to regret anything we have written.

#### THE METRIC SYSTEM AND OTHER MATTERS.

J. F. BALDWIN, Professor of Physiology in Columbus Medical College, and one of the Editors of the *Ohio Medical Recorder*, criticises our recent articles on the metric system in a manner that is quite refreshing. His main argument appears to be that the metric system is altogether too complicated to be comprehended by the average medical mind. Judged from an Ohio standpoint, this may be the case, for Dr. Bates says as follows: “About a year ago I attended a large gathering of about a dozen exceedingly intelligent medical gentlemen. During the evening it became desirable to know the length of a *centimetre*; not one of these gentlemen was able to give it, their *approximations* varying from half an inch to an inch and a half.” Does the Professor include himself in the number? If “a dozen exceedingly intelligent” Columbus physicians were thus ignorant of a matter which is fully explained in the U. S. Dispensatory, what must be the status of the remaining physicians in Ohio, who, in contradistinction, are not “exceedingly intelligent”? The Professor further regrets that we did not give a translation of the quotation, *mensuris nunquam, sed semper ponderibus, liquorum quantitas indicanda et determinanda est*, and remarks that our neglect to do so savors of “conceited pedantry.” Really, we think that the criticism of the Professor is an insult, not only to the medical men of Ohio, but to the intelligence of the profession at large. This attempt to make ignorance respectable is perhaps best explained by the encouragement which is given by the Professor to cheap medical education. It is in fact one of the strong arguments in favor of a college which furnishes matriculation and professors’ salaries for \$30—an argument in favor of debauching the ploughshare and the anvil, men who might be useful citizens in appropriate stations, but who, to embrace a profession for which they are not qualified, reflect their ignorance and incapacity on the pro-

fession as a whole. Will the *educated* physicians of this country never awaken to the fact that every ignoramus armed with a diploma, is an enemy, not only to the public, but to the profession itself. Why does Homoeopathy flourish more luxuriantly here than abroad? Partly because there is so little contrast between them; so many of our own men to whom the Latin sentence above written would prove a “*pons asinorum*.” If, however, the medical profession of Ohio are willing to give their moral support to \$30 colleges, they must expect to realize the truth of the old proverb, “Poor pay, poor preach,” and its natural consequences.

## Reviews and Notices of Books.

A DIRECTORY FOR THE DISSECTION OF THE HUMAN BODY. By JOHN CLELAND, M.D., F.R.S., Professor of Anatomy and Physiology in Queen's College, Galway. Philadelphia: Henry C. Lea. 1877, pp. 182.

This little book is intended to replace at the dissecting table the larger descriptive works that students so frequently employ, the author believing that it is better to study these latter thoroughly at home, and to have but an outline guide, as it were, by the side of the “subject.” After preliminary chapters on “The Use of Instruments” and “The Order of Dissection,” the author proceeds to a clear and graphic account of the principal features of the several regions, neglecting, of course, the minor details. The work, on the whole, is a welcome addition to our rather scanty stock of small but good dissecting manuals.

THE PRACTITIONER'S HANDBOOK OF TREATMENT; OR, THE PRINCIPLES OF THERAPEUTICS. By J. MILLNER FOTHERGILL, M.D., Member of Royal College of Physicians of London, etc., etc. Philadelphia: H. C. Lea. 1877. 8vo, pp. 577.

This work is very aptly named, and for such as are in search of the “thoroughly practical” method of studying diseases, will be appreciated accordingly. It is somewhat difficult to give an idea of its scope, as its system of arrangement is not very definite, and the discussion of its subjects is desultory rather than logical. This, considering the general character of the work, is not depreciative criticism. In fact, under the circumstances, an arbitrary arrangement of subjects would detract from the real interest of the work. The author, however, makes an attempt to be systematic, but his desire to impart practical information is too strong to enable him always to stick to his text. For instance, he starts with the intention of laying down principles governing the laws of disease, and constantly dovetails some practical hint connected with the treatment of a particular disease, and not infrequently gives a prescription. But this is a virtue rather than a fault, in connection with the main object he has in view. His work gives one the impression of a familiar talk upon the practice of medicine, profusely illustrated with valuable practical hints. No one can read it without being impressed with the immense amount of common sense which is possessed by the author, as well as natural tact in interpreting the indications of treatment. His style is clear and agreeable, and he has the faculty of expounding the fundamental principles of medicine in such a way as to

give them a practical application to treatment. We shall not attempt to enumerate the number of diseases to which he refers; suffice it to say that they extend over a wide range of practice, and that their careful study will amply repay every busy worker in our ranks. It is, in fact, one of the most interesting, entertaining, and instructive works of its kind we have ever read.

VALEDICTORY ADDRESS, IN BEHALF OF THE FACULTY, MED. DEPART. UNIV. OF CALIFORNIA. By F. W. HATCH, A.M., M.D. San Francisco, 1876.

VALEDICTORIES are rarely more than farewell partings, expressed in parental language, warning the newly-fledged M.D. against the perils of the future, and pointing out to him the channels through which he must steer to attain success. Dr. Hatch avoids in a great measure the usual platitudes of the occasion, and briefly indicates the advantages which recent students have over those of former years.

OBSTETRICS AND GYNECOLOGY 100 YEARS AGO. An Introductory Lecture, by PROF. ALEX. RUSSELL SIMPSON, President Edinburgh Obstetrical Society. London, 1876.

THIS brochure, now republished from the *Obstetrical Journal* of December, 1876, was inspired by a recent visit of its author to this country at the time of the session of the International Medical Congress. After paying a complimentary tribute to those who, by their contributions to obstetrical literature, aided to make that gathering a memorable one, he devotes the chief portion of his lecture to an exceedingly interesting review of the old-fashioned procedures and undeveloped views of the obstetricians and gynecologists of 100 years ago.

LESSONS TO BE LEARNED FROM THE CHOLERA FACTS OF THE PAST YEAR, ETC. By ELY McCLELLAN, M.D., Surgeon U. S. Army. Louisville, 1876.

THE author of this pamphlet (originally printed in the columns of a contemporary) seems to have identified himself conspicuously during the few years past with cholera progress and statistics. After alluding *in extenso* to the march of the disease in Syria and other oriental countries, and its recent history in the United States, he submits the following propositions: 1 Asiatic cholera has never yet originated upon the North American continent, but has invariably reached its shores after it has been transported across the Atlantic Ocean. 2. It is diffused by migrations of individuals infected with the disease; in their dejections there exists an organic matter, at a certain stage of development capable of reproducing the disease in the alimentary canal of other persons; articles of clothing, merchandise, furniture, etc., infected by soiling with the excreta of cholera cases, retain indefinitely their power of infection, and may be the means of conveying the disease to a distance. The remedies are: 1, prevent its importation; 2, stamp it out after it gains access.

TWENTY-NINTH ANNUAL REPORT OF THE TRUSTEES OF THE MASSACHUSETTS SCHOOL FOR IDIOTIC AND FEEBLE-MINDED YOUTH. October, 1876.

AFTER paying a deserved tribute to the memory of Dr. Howe, to whose efforts this institution owed so much of its success, the report dwells on the good results that have been attained by the system pursued in it, by which more than three-fifths of the 548 idiotic youth enrolled as pupils have been improved either physically, morally, or intellectually, and raised in the scale of humanity.

## Reports of Societies.

### NEW YORK MEDICAL JOURNAL ASSOCIATION.

*Stated Meeting, February 2d, 1877.\**

DR. CHARLES M. ALLIN, PRESIDENT, IN THE CHAIR. PRACTICAL POINTS IN THE ELECTROLYTIC TREATMENT OF CYSTIC AND FIBROID TUMORS.

DR. G. M. BEARD'S paper (*vid.* p. 161) being open for discussion.

DR. ROBERT NEWMAN remarked, with regard to application of the needles, that he did not agree with Dr. Beard. For, if a positive pole was applied close to a negative one, a disturbance was created which, if possible, should be avoided. Now, if the positive pole was applied at a large distance from the tumor to be operated upon, applied in the hand, for instance, where we had a simple conductor, all the action was concentrated in the negative pole and without disturbance.

Dr. Newman spoke in the most commendable terms of the power of electrolysis for the relief of pain, especially in cases of carcinoma of the breast. The doctor took a rather liberal view regarding the efficacy of the electrolytic treatment of malignant tumors, thought that in cases in which the axillary glands speaking of scirrhus of the breast—were not involved or the glands nearest to the growth in any case, surface of the skin not broken, there was no suppuration or hemorrhage, and the treatment was commenced early, there was a fair chance to cure the disease. Regarding the beneficial effect produced upon ovarian tumors by this plan of treatment, he expressed some doubt. If the cyst was unilocular, it might perhaps, be cured as well as a hydrocele; but in treatment of a multilocular cyst the result was probably much more questionable.

DR. BEARD remarked that in medical electricity practical difference between the two poles was one of degree; whereas in surgical electricity the practical difference was almost in kind.

DR. F. N. OTIS inquired regarding the results obtained by the electrolytic treatment of ordinary glaucoma, hyperplasia or adenoma.

DR. BEARD replied that simple adenoma or glaucoma enlargements were more unfavorable for treatment than even malignant growths. When they were hard and large they were not pleasant to treat, for the reason that they did not readily disappear.

DR. NEWMAN'S experience in respect to this class of tumors had been the same as Dr. Beard's, and although he had seen cases in which the enlargement of the glands rapidly disappeared, it very soon returned. The size of the affected gland was reduced, but the general cause remaining, it was soon retainted.

DR. BEARD remarked that, in general, the best results were obtained in the treatment of naevi of the face; next, in the treatment of cystic tumors of benign character; then followed fibro-cystic tumors, then came epithelial cancers of the face, taken up and treated by electrolysis at the base; and next in order were malignant tumors in different parts of the body. It was thought that, perhaps, fibroid tumors go before malignant tumors, but the tumors in which the least favorable results had been obtained were adenomas.

\* This report has been delayed until this time in order to accompany Dr. Beard's paper.—Ed.

R. R. P. LINCOLN inquired whether more malignant tumors had been cured than simple fibroids?

DR. BEARD replied that he did not think a very large number of either variety had been cured. He was inclined to the opinion that, perhaps, so far as favorable results were concerned, fibroids should present malignant growths. For it had not been determined whether malignant tumors had been cured, or cause if the tumor under treatment had been cured, as at once said that it was not malignant.

DR. LINCOLN referred to four cases of goitre, in which, without the aid of internal remedies, he had succeeded in completely removing the tumor by means of the electrolytic treatment. He had employed a small-sized battery, and made each *séance* from ten to twelve minutes.

DR. BEARD, in reply to a question, remarked that he had seen one case of exophthalmic goitre completely cured by means of electricity.

A member referred to four cases of ordinary goitre in which the pulsation had been materially diminished by the use of electricity; he had also used it in one case of exophthalmic goitre, but without affording relief.

Some discussion followed with reference to the difficulty in removing the positive needle, and the best means by which such difficulty could be avoided. The opinion which seemed to prevail was that the difficulty could be best overcome by simply reversing the current until the positive needle was loosened. The Association then adjourned.

## MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, February 26, 1877.

DR. J. C. PETERS, PRESIDENT, IN THE CHAIR.

### NEW MEMBERS.

In accordance with a recommendation from the Committee on the *Minora*, it was voted to grant certificates of membership to Drs. Albert A. Davis, G. F. Bates, Frank Blumenthal, J. F. Golding, C. R. Bogert, Frederick Bedford, John Osborn, Charles K. Briddon, and M. Beckman, M. S. Buttles, J. H. Eden, and A. Dana.

### HYPOXANTHINE—CHEMICAL ANALYSIS OF THE BLOOD IN LEUCOCYTHÆMIA.

DR. CHARLES A. DOREMUS gave the result of chemical analysis of blood taken from a patient suffering with leucocythæmia. The clinical history of the case has been reported to the Society some time previously by Dr. E. G. Janeway. On account of the deficiency of the quantity submitted for analysis, hypoxanthine was not found in the urine. The quantity of blood examined was three ounces, and by careful chemical manipulation positive evidence was obtained that hypoxanthine was present. Specimen crystals were exhibited with the microscope.

### RELATIONS OF THE URINARY ORGANS TO PUERPERAL DISEASES.

DR. W. M. CHAMBERLAIN read a paper upon the above subject, and reached the following conclusions:—1. Acute erysipelatous inflammation of the external genitalia might ascend to the kidney, sometimes by the inner and sometimes by the outer surface of the urinary tract.

2. The blood of the parturient woman, saturated with fibrine and poor in hæmoglobin, predisposed her to disease of the excretory organs—the kidneys and

liver. With a sufficient exciting cause, acute fatty metamorphosis occurred. Fatal cases only were demonstrable, but minor grades of the process were probably not infrequent.

3. Limited lymphangitis (or cellulitis) and diffuse lymphangitis might mechanically induce acute œdema of the kidney in the puerperal woman by obstruction of the ureter.

4. Diphtheritic or other inflammation involving the muscular coat of the bladder produced the same result.

5. Edema of the kidney, however produced, favored rapid degeneration both of the tubular and inter-tubular structure.

6. Diffuse lymphangitis, commonly attending septic processes, by reason of rapid destruction of the hæmoglobin, favored the same result, while ulcerative endometritis, suppurative metrophebitis and cellulitis, tending to pyæmia, not unfrequently were productive of metastatic suppurative nephritis.

7. The condition known as uræmia favored the development of peritonitis in parturient women.

The paper was discussed by Drs. Barker and Putnam-Jacobi.

## Correspondence.

### PUERPERAL FEVER AT CHARITY HOSPITAL.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—The editorial in a recent number of your journal is calculated to do an injustice, inasmuch as it is based upon some sad misapprehension. That there has been puerperal fever in Charity Hospital since the removal of the lying-in service from Bellevue to its wards is a fact, but that it has ever reached the dimensions of an "epidemic," in the sense your article would convey, is a mistake.

During the three years 1874, 1875, and 1876, there have been 1,387 deliveries in our service, and 11 deaths from puerperal fever. This would make our average mortality from this cause 0.79 per cent., say about three-quarters of one per cent.

Do you know a maternity of equal magnitude to Charity presenting any better report than this?

You say with regard to our management: "Regardless of the experience of the past, the old routine has been resumed, with a result corresponding to what might have been expected." Comparing this statement with the facts, the only agreement I can find is that the service has been continued from time to time within the halls of the General Hospital building. This has been no detriment to the service in the sense that the service thus situated at Bellevue was detrimental, for our wards are larger by far, flooded with light and air from windows upon three sides, extending almost to the ceiling.

Surrounding the hospital, as you know, is a magnificent expanse of water and park, and there is no one to dispute that there is anywhere in the land a more delightful and salubrious spot than where these patients are cared for.

The lying-in wards are thoroughly policed, and no visitors are permitted to enter them. Even the house physicians and surgeons, on duty elsewhere, are forbidden to enter; nurses, officials, patients—indeed, every one is excluded from that part of the hospital except those who may be on duty there.

The "waiting" women are not allowed to com-

mingle with the other patients. They are under so many restrictions that at times they feel they are prisoners. It is needless to tell you that every precaution in the direction of personal and ward cleanliness is observed, and, moreover, that clinical exhibition of the women is interdicted. It would surprise you, if you had time to inquire into the conservatism of our practice. The forceps are rarely applied, and other operative procedures are so rare as to put the service on a plane with private practice.

Our mortality from all causes combined is 2.50 per cent., and this, mind you, is among a class of women who come to us broken in health and morals. Forty-five per cent. are unmarried, and all are representatives of the most wretched and hopeless class in the community.

During the latter part of January, puerperal fever started, and two of our patients died. No doubt this would have become an epidemic had we not stamped it out at once by our usual means—and these very means exist in the abundant room and facilities the hospital and its outlying pavilions afford. The "waiting women" were at once transferred to pavilion C (which had been occupied by epileptics), and an entirely new set of nurses and house physicians put in charge. The women (five) already sick were quarantined in the wards they occupied, with the doctors and nurses who had them in care at the time of their attack. Those convalescent and all others not sick were distributed to another ward, with a new and special set of attendants. The women who had been sent to the pavilion were subjected to daily baths of carbolized water, their clothing was changed throughout, and every effort, hygienic, police, and quarantine, exerted in their behalf. The result was, as we expected from former experience, that not another case of fever occurred, either in this class or the convalescents left in the hospital.

You will pardon this perhaps immaterial matter in my communication, but it seems necessary to show you that our routine is in no respect like that charged in your article.

In a short time we expect to remove the service to its new quarters near the Alms-house, in pavilions especially erected for the purpose. They are in process of construction at present. Although it would perhaps be better to construct such hospitals after the direction of hygienists, and in a form which would permit destruction by fire or otherwise upon the occurrence of this fatally contagious disease, yet, if submitted to our taxpayers, I doubt whether they would encourage us to add to their debts, for the purpose and class interested. This idea is Utopian, and all we can hope to do is to control and prevent this disease by all vigilance and care.

It is as suppressible, when once it has started, as small-pox, and we never have failed to check it in Charity, and we never shall fail (our statistics prove our position) unless we are hampered and discouraged by sentiments (which may take form and action) such as your article was calculated to inspire.

Very respectfully,

WALTER R. GILLETTE, M.D.,

VISITING PHYSICIAN, LYING IN SERVICE, CHARITY HOSPITAL.

## QUININE AND HYDROBROMIC ACID.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—In No. 329 of THE RECORD is an article from "M. D." representing the danger of prescribing hydrobromic acid. The writer thinks that through a communication from me, in No. 320 of THE RECORD,

a Brooklyn physician might have poisoned one of his patients, but for the remarkable, discriminative intelligence of a Brooklyn druggist.

I am truly sorry that I have jeopardized the lives of the Brooklyn people. My position is this: The statements of Fothergill, of London, in regard to the value of hydrobromic acid in preventing head symptoms following the use of quinine, led us to try the remedy at the hospital, and I ventured to present the results of its use. Inasmuch as the formula for preparation was distinctly and clearly given, and the manner of using it, I ought not to be held responsible for the ill effects of Merck's or any other preparation of hydrobromic acid.

"M. D." regrets that we have not an official preparation of dilute hydrobromic acid. Until we have such an official preparation we cannot do better than use the preparation made according to Fothergill's formula, a preparation so simple that any druggist can make it.

Further employment of this medicine but confirms my former favorable opinion of its merits, and further observation of the uncomfortable "head symptoms" of cinchonism convinces me that we should employ something to prevent such manifestations.

For a statement of the therapeutic use of hydrobromic acid I would refer to the Oct. number of the *American Journal of Medical Sciences*. A writer in the January number, 1875 of the *American Journal of Medical Sciences*, in speaking of Dr. Hammond's and Dr. Roosa's experiments with quinine, which show that sulphate of quinine causes hyperemia and congestion of the brain, adds: "And we have had many treatment cases of amaurosis, sometimes utterly irreparable, occasioned by the too free use of quinine."

If some cases of amaurosis from the use of quinine have been recorded, we may well believe that there are more cases that have not been recorded, so that continued use of large doses of quinine not only causes uncomfortable head symptoms, but irreparable injury to the organs of sight and hearing.

W. E. FOREST, M.D.

PRESBYTERIAN HOSPITAL, March 5th, 1877.

## COLEMAN'S MULTIPLE WEDGE IN THE TREATMENT OF STRICTURE.

The following correspondence will explain itself:

Augusta, Georgia, Feb. 17th, 1877.

DR. AXEL IVERSON, *Copenhagen, Denmark*.

MY DEAR SIR:—In your review of the disease of the urethra in Virchow's *Year Book* for 1876 you do me the honor to notice my multiple wedge principle in the treatment of stricture. Your comment is as follows: "Recommendation of the introduction of several thin bougies alongside of each other for gradual dilatation according to the well known manipulation of Bénéiqué." From this I think that you have mistaken the idea of the principle intended to convey. My knowledge of Bénéiqué's method is traditional, as I have never seen his method. He uses a large number of instruments, *one after the other, and not side by side*, as I do in my multiple wedge.

In proof of this assertion I make the following extract from a review of his little book, in the March number of the *Archives Générales de Médecine*, 115, p. 390: "He introduces into the urethra a large, whose volume varies according to circumstances. As soon as it has penetrated it is *withdrawn*," and

\* Italics my own.

one voluminous one introduced. Thus *in succession* three or four bougies, each larger than the other, are employed in the space of two or three minutes. The next day he introduces the bougie which had been last used on the preceding day, and several others, increasing in size in the space of some minutes. Thus he continues every day until he succeeds in the production of the largest bougies, which are not permitted to remain in the urethra for a longer period."

To quote from my article. I say: "It ought to be a self-evident proposition that it is easier to introduce *gradually* the component parts of a wedge, than to introduce it as a whole. Take, for example, a No. 12 medical bougie, even capillary at its point, and attempt to introduce it into a stricture, where is the point of friction and resistance? Is it not around the entire circumference of the stricture? Diminish the size of the instrument and in a direct ratio you diminish the amount of resistance. After having passed into a stricture one of these (Gouley's) whalebone guides,\* the second has to overcome the friction and resistance but one-half the circumference of the stricture and a line of contact with the other bougie. Now that we have passed these two, we have a groove in front and behind them through which we can readily pass a third and fourth, having now to overcome the resistance of but one-fourth the circumference of the stricture and the *two lines of contact* with the instruments already in position."

The application of this principle to the "continuous method" of dilatation surpasses all other treatments known to me.

Very respectfully,  
JNO. S. COLEMAN, M.D.

## LEUBE'S MEAT SOLUTION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—You will oblige many of your readers, who are subscribers to "Ziemssen's Cyclopaedia of the Science of Medicine," by giving publicity to the formula below, for the meat-solution recommended by Leube in his article on "Diseases of the Stomach and Intestines," contained in the seventh volume of that work. A note appended to the article by the translator unfortunately contains an important error. The meat is *not* digested with a strongly acid solution of *sin*; in fact, Leube expressly states in the *Berliner ärztliche Wochenschrift*, No. 17, 1873, that the use of *sin* imparts so offensive an odor of vomited matters to the preparation as to render it useless for therapeutic purposes. The formula as there given is as follows:

"Take 1,000 grammes of beef, free from fat and water, put into an earthen or porcelain jar, and add 100 c.c. of water, and 20 c.c. of pure hydrochloric acid. After placing the jar in a Papin's digester, close the cover tight, and boil from ten to fifteen hours, stirring occasionally during the first few hours. Then remove the contents of the jar to a mortar, and pound the mass until it has the appearance of an emulsion. Boil again for fifteen or twenty hours without the cover of the digester. Add pure potassium carbonate until the mass is nearly neutralized, and then incorporate to a pulpy consistence."

At the time of the translation of Leube's article in the *Cyclopaedia*, I was unaware that this meat-solution for some time past been successfully prepared by Fred. Hoffmann, apothecary, 797 Sixth Avenue,

corner 45th Street. The jars imported from Germany have failed to give satisfaction, partly because many of them have become spoiled, and partly because in others the process of emulsification has been imperfectly effected. Mr. Hoffmann has made some changes in the formula, which may be regarded as improvements. He adds only one-tenth water instead of equal parts, and omits the final evaporation in order to avoid exposing the solution to the air. He also substitutes the sodium for the potassium carbonate, as less likely to irritate the stomach, and continues the boiling each time for a considerably longer period. The result is a complete and not unpalatable emulsion, which will keep perfectly in the sealed vessels as long as three weeks, and even longer if a little salicylic acid have been added. Representing, as it does, the *entire* ingredients of the beef used, the preparation certainly deserves a thorough trial as a rational substitute for our innutritious beef-teas and beef-extracts.

A. B. BALL.

28 W. 36TH STREET.

## THE TREATMENT OF WHOOPING-COUGH.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—In the month of November I was called to attend two cases of whooping-cough, occurring in two sisters with the respective ages of thirteen and twenty-four years. It was upon the fifth day of the attack. The eldest had coughed the greater part of the two preceding nights, and consequently had hardly slept at all. The younger sister, though not so severely afflicted, had the previous night, by her mother's count, thirty paroxysms of coughing, and all of them quite severe. Having read Steffen's description of Benz's method of treating whooping-cough with quinine, as given in "Ziemssen's Cyclopaedia," I determined to try it. To the eldest I prescribed five grains of the quinia each four hours. To the youngest I prescribed the dose of eight grains to be given twice daily. In these two cases the results were almost marvellous; for the eldest, after having taken sixteen grains, slept all night; the youngest did equally well on the eight grains. The paroxysms after the third day's use of the quinine were not beyond four in number, and at the end of eleven more days I considered them cured. There was no return of the cough after omitting the remedy.

Six weeks later, three more cases of equal severity came into my hands, and under the same treatment did equally well. In all I have treated eleven cases by this method, and each of them have had equally conclusive results; inasmuch as to make myself, as well as the patients, well satisfied with the kind of treatment.

DAVID DANA SPEAR, M.D.

FREEMONT, ME., Jan. 31, 1877.

## ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from March 4, to March 10, 1877.*

BYRNE, C. B., Asst. Surgeon. Assigned to duty at Fort Duncan, Tex. S. O. 40, Dept. of Texas, March 2, 1877.

SHANNON, W. C., Asst. Surgeon. Relieved from duty at Fort Duncan and assigned to temporary duty at Fort Clark, Tex. S. O. 40, C. S., Dept. of Texas.

\* Or the French filiform elastic bougie.

## Medical Items and News.

**CONTAGIOUS DISEASES.**—Comparative statement of cases of Contagious Disease reported to the Sanitary Bureau, Health Department, for the two weeks ending March 10, 1877.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-Spinal Meningitis.	Measles.	Diphtheria.	Small-pox.
March 3 . . . . .	0	5	82	3	7	48	0
" 10 . . . . .	0	5	90	3	7	57	1

**THE HEALTH OF SCHOOL-CHILDREN.**—At the regular monthly meeting of the East River Medical Association of this city, held Feb. 13, 1877, the following preamble and resolutions were adopted unanimously:

*Whereas*, Of its importance in protecting the health of school-children, and promoting the interests of school sanitation, we earnestly recommend the bill introduced by the Hon. James W. Gerard, providing for medical supervision of the Public Schools in the city of New York.

*Resolved*, That the East River Medical Association deems it necessary that additional safeguards be adopted to protect the health of children in the Public Schools, and will unite with the Medico-Legal and other medical societies in petitioning the Honorable Legislature for the passage of the bill.

*Resolved*, That the Secretary be directed to transmit to the members of the Legislature from the City and County of New York a copy of these resolutions, and that they be earnestly requested to do all in their power to further this measure.

**PROPHYLACTIC FOR VENEREAL DISEASE.**—Pavesi recommends the following as a prophylactic lotion against venereal disease:

B. Chloral hydrat.,	
Acid. salicylic.,	
Sodæ Sulphit.,	
Glycerin . . . . .	1.50
Aque . . . . .	4.
Alcohol . . . . .	1.00

M.

The ingredients to be mixed and maintained at a gentle heat till dissolved, then filter.—*Giornale Italiano delle Mal. Vener. e della Pelle.*

**SCARLET FEVER.**—A correspondent desires answers to the following questions:—Can there be an epidemic of scarlet fever in which the absence of eruption is the rule; an appearance of eruption but occasionally? What, if any, is the pathognomonic of scarlet fever? What character as an infectious fever has scarlet fever? What character as a contagious disease has scarlet fever? Has scarlet fever an invariable natural course? If so, what is its duration? Is it probable that during an epidemic visitation in a town of twelve thousand inhabitants, but one hundred cases would occur, and their occurring would be in different and widely separate houses, without communication between the inmates of the several houses? Is it probable that having entered a house the scarlet fever will fail to attack the majority of the inmates who had never been sick with scarlet fever? Is it probable that an epidemic of scarlet fever can occur in the midst of twelve thousand inhabitants and only one

hundred cases occur, and consuming four to eight weeks in occurring? Is it probable that one hundred cases of scarlet fever can occur in such a number of inhabitants, and only one of the number die? What is the lowest mortality of (rate) scarlet fever?

**NEW YORK PHYSICIANS' MUTUAL AID ASSOCIATION.**—The eighth annual report shows the following figures:

The total number of members during the year was 338; died, 7; dropped from the list for non-payment of dues, 5; present number, 326.

The permanent fund (November, 1876), amounts to \$3,428.60, invested in United States bonds, and placed in a trust company.

As a matter of interest to members, a concise statement of the total receipts and expenditures of the Association since its organization in July, 1868, is appended:

Total amount of assessments collected . . .	\$14,202
" " paid to families of deceased members . . . . .	11,740
Donated to permanent fund, or passed to account of contingent fund, as required by by-laws . . . . .	2,462
Total expenses since July, 1868 . . . . .	1,038
Permanent fund now amounts to . . . . .	3,777

It will be seen from the above statement that the Association is in a healthy financial condition; that a large amount of money has been collected and disbursed; that the distribution is prompt and satisfactory; and while all possible economy is practised in the items of expenditure, the permanent fund is slowly but surely increasing.

With no salaried officers, and the free-use of the council-room of the Academy of Medicine, where the meetings of the Board of Trustees are held, the means of expense have been for printing, postage, and special services.

Dr. Mark Blumenthal is President, and Dr. David Magie, Recording Secretary.

DR. D. H. KITCHEN has resigned as Chief of Staff of Charity Hospital to accept the appointment of Medical Superintendent of the N. Y. State Inebriate Asylum, at Binghamton, N. Y.

**MASSACHUSETTS CHARITABLE EYE AND EAR FIRMARY, BOSTON, MASS.**—The annual report of this institution, recently published, shows a steady increase of patronage for the past ten years. During last year 8,452 cases were treated, and of these 413 were hospital patients. Besides other interesting features, the report contains a statistical account of fifty operations for cataract by Von Graefe's method. The infirmary has no private rooms, and its patients come solely from the ranks of the poor. The following gentlemen compose the staff of surgeons: Drs. Hasket Derby, Henry L. Shaw, F. P. Sprague, B. Joy Jeffreys, Rollin Willard, and Clarence J. Blake.

**SCIENCE VS. FRAUD.**—A case was recently tried in Albany in which damages were claimed by a person on account of an alleged loss of the sight of one eye caused by an accident on a highway which was in an unfinished and dangerous condition. The principal line of defence rested upon the assumption that no injury of sight was sustained, a fact which was convincingly proved to the jury by Dr. Charles A. Robertson, of the city. The verdict was in accordance with the facts, and the town of Halfmoon, in which the highway was situated, was saved the sum of ten thousand dollars damages.

## Original Communications.

## THE DANGER ATTENDING THE INTRODUCTION OF FLUIDS INTO THE NASAL PASSAGES.

By ALBERT H. BUCK, M.D.,

NEW YORK.

As long ago as 1869 Dr. Roosa, of this city, called attention to the fact that the use of Weber's nasal douche sometimes gives rise to serious inflammation in one or both ears. Since then other surgeons in this country (Knapp and Pardee, of this city, Shaw, of Boston, and Bowen, of Hartford) have reported a number of cases in which the same unfavorable results followed the employment of this method of treatment. In spite of these warnings, I have reason to believe that the nasal douche, or some substitute for it, is still widely recommended by physicians to their patients; and I therefore do not consider it out of place at the present time to add my testimony to that already given in favor of greater caution in the use of this and similar methods of introducing fluids into the nasal passages.

The prevailing belief seems to be that, if certain precautions be observed, the douche may be safely employed. These precautions are: the fluid must be sufficiently warm; it must not be introduced under too great pressure; there must be no obstacle in its way as it passes into one nostril and out through the other; and, finally, the patient must be distinctly warned not to swallow during the continuance of the procedure. If during this time no fluid finds its way into either tympanic cavity, the danger of exciting an inflammation of this part of the ear is generally believed to be at an end. It is evident, therefore, from this belief, and from the precautions which have just been enumerated, that the chief, and apparently the only, danger is thought to be connected with the entrance of a part of the fluid into the middle ear during the actual use of the douche; in other words, the danger is supposed to be at an end when the pressure upon the fluid is withdrawn. Many physicians have accordingly abandoned the use of the nasal douche, and employ in its place the posterior nares syringe, the atomizer, or the "snuffing-up" process, believing these to be quite safe methods, as little or no pressure is used. Shaw, however, has recently shown that the posterior nares syringe and the snuffing-up process may also give rise to ear trouble. It is evident, therefore, that the theory very generally adopted in explanation of the aural complication is not the correct one for all cases.

My entire experience in this matter is summed up in the briefest possible manner in the histories of cases appended to these remarks; and it will there be seen that the introduction of a fluid into the nasal passages in a sufficiently large quantity to bathe the orifice of the Eustachian tube (no matter by what method it is introduced) is not wholly free from the danger of setting up an inflammation of the middle ear. As stated by the patients themselves, the fluid is forced into the ear by the act of blowing the nose subsequently to the introduction of the fluid into the nasal passages. The depression corresponding to the orifice of the Eustachian tube is adapted by its very shape to retain, for a short time at least, a drop or two of the fluid which has been made to bathe its lips. From this position the adherent drop of fluid is undoubtedly forced up into the cavity of the tympanum, immediately the

patient supplies the necessary *vis à tergo* by blowing his nose, which patients are instinctively led to do very soon after the employment of any of the methods mentioned above.

So far as I am aware, no cases have as yet been reported where inflammation of the middle ear followed the use of the atomizer, the spray being introduced either by way of the naso-pharyngeal space or by way of the anterior nares. If a sufficient amount of spray, however, be introduced, I cannot see why the danger is not just as great under these circumstances as when the other methods are used. Instantaneous spraying can simply cover the entire mucous membrane with an exceedingly thin layer of fluid, and consequently must be a perfectly safe proceeding; but continuous spraying, kept up for a quarter of a minute or half a minute, must introduce into the nasal passages as large a quantity of free fluid as would, for instance, the snuffing-up process. As regards the quality of the fluid used, all the solutions generally employed—simple water not excepted—seem to be more or less irritating to the mucous membrane of the middle ear, though solutions of salt appear to produce the most violent forms of otitis media. The acute attacks of inflammation of the middle ear, which are so common after bathing in salt water, are probably to be explained in the manner described above; the bather dives, swims under water, and in one way or another introduces quite a large quantity of salt water into the nasal passages; and upon reaching the shore one of his first acts is to clear out his nasal passages by blowing the nose forcibly. In this way some of the salt water finds its way into the middle ear.

It is greatly to be desired that those physicians who have made extensive use of these different methods of bathing the nasal passages should give us the exact proportion of cases in which disturbances in the ear have followed the treatment. Such a statement would show more accurately the degree of danger incurred than does such a report as the one here submitted.

Many will be very likely to ask themselves the question: If these different methods of treatment, which we know by actual experience to be often beneficial, are attended with danger, what is left for us to do in the treatment of these annoying and obstinate catarrhal affections? To answer this properly would lead me too far. I would say, however, that my own preferences have induced me to employ, almost exclusively, the so-called swabbing method, the applications being made to the naso-pharyngeal mucous membrane only, and the remedy used being nitrate of silver, in solutions of varying strength (from gr. xx. to gr. xlv. to the ounce of water). To my knowledge not a single unfavorable result has ever followed the use of this plan of treatment.

CASE I.—1871. Male; *ætat.* circa 40. Snuffed up some water to which a little salt had been added. Almost immediately afterward he was seized with a severe pain in one ear. Acute purulent inflammation of middle ear. Rupture of membrana tympani. Otorrhœa lasting a few days. Recovery without appreciable loss of hearing.

CASE II.—1873. Male; *ætat.* 19. Consulted a physician for naso-pharyngeal catarrh. Treatment consisted, among other things, in the injection of a weak astringent (sulphate of zinc) solution into one nostril, and out through the other. In my notes of this case it is not stated how often this procedure had been carried out, but shortly after one of his visits to the physician's office he was seized with pain in one ear. This lasted for two days, but was of only mode-

rate severity. Deafness quite noticeable. Inspection shows evidences of an acute catarrhal inflammation of the middle ear (Shrapnell's membrane red and edematous; at its junction with posterior superior quadrant of memb. tymp., a small bleb containing bloody serum; edematous condition of dermoid layer of membrana tympani). Inflammation subsequently subsided without passing into an otitis media purulenta.

CASE III.—1875. Male; ætat. 72. About three weeks ago, as he states, snuffed up cold salt and water into the nostrils, and afterwards blew his nose. Since then has been quite deaf in one ear. Had pain in the ear the same day, and occasionally since. Examination reveals evidences of a subacute otitis media catarrhalis. (Patient not seen again; he lived at a distance from the city.)

CASE IV.—1875. Female; ætat. 20. Purulent inflammation of both middle ears of ten days' standing. According to statement of attending physician, pain manifested itself in both ears after use of nasal douche. The pain continued for a short time, and then abated upon the establishment of a double otorrhœa. Inspection shows both tympanic membranes perforated. Abundant discharge of pus. (Case seen in consultation; no further data noted.)

CASE V.—1876. Male (a physician); ætat. 34. States that on preceding day used nasal douche with warm salt and water. Observed all the precautions laid down in the books. Both ears soon afterward became painful. In the left ear the pain rapidly became severe. This morning no pain in right ear, and but little in the left. Inspection shows slight congestion of right membrana tympani (peripheral and manubrial portions); on the left side, the congestion is more decided. Later in the day the pain became violent in the left ear, and three leeches were applied. During the night a slight escape of blood from the left ear. The following morning I incised the membrana tympani, and evacuated two or three drops of bloody serum. Relief from the pain. Five days later, a second incision. The subsequent progress of the case toward recovery, of no special interest.

CASE VI.—1876. Male; ætat. 63. Upon the advice of some friend, has of late been in the habit of snuffing up water (of the ordinary temperature of the Croton in April) into the nostrils. Has on several occasions noticed unpleasant sensations in the ears after the procedure, but never any real pain until four days ago. Since then the pain in the right ear has steadily increased in violence. Membrana tympani (right) swollen and bulging posteriorly. Free incision gave escape to bloody serum. Marked relief followed. Recovery afterwards took place slowly, the otorrhœa persisting for nearly two months.

CASE VII.—1876. Male; ætat. 5. Two days previously a warm weak solution of salt had been injected into the nostrils from behind by means of a posterior nares syringe—the boy at the time suffering from an active naso-pharyngeal catarrh. Almost at once the child complained of pain in both ears. On the morning of the third day, both tympanic membranes being red, edematous, and bulging (posteriorly), I punctured them, but not as freely on the right side as I should have done. In the evening, incised the right membrane more freely, giving escape to bloody serum. The following day—there having been a free watery discharge from both ears during the night—the pain had entirely disappeared, and recovery followed in the course of a few days.

CASE VIII.—1876. Male; ætat. 36. Nasal douche with weak solution of salt used for several days without any unpleasant effects. On one occasion, however,

shortly after the douche had been used, patient blew his nose, and was conscious at once of something having entered one ear. In less than two hours the pain in this ear had become quite severe. Great suffering during the following twenty-four hours. An incision in the membrana tympani then gave speedy relief. Otorrhœa continued for about a week. Recovery.

CASE IX.—1877. Male; ætat. 35. States that two days ago he snuffed up a weak aqueous solution of salt into the nostrils, and afterwards "blew his nose;" that he was conscious at the time of something having "given way" in the right ear; that after the lapse of a few minutes the ear began to ache, and that the pain rapidly increased to such a pitch, that he could neither sleep nor eat. Inspection reveals evidences of an active inflammation of the right middle ear, with bulging of the posterior half of the membrana tympani. Free incision giving escape to bloody serum. Pain ceased entirely after the lapse of two or three hours. Free discharge of a watery nature. Subsequent recovery rapid.

CASE X.—1877. Female; ætat. circa 30. Has quite recently been in the habit of snuffing up a weak aqueous solution of salt into the nostrils for the relief of a naso-pharyngeal catarrh. On more than one occasion has noticed, after blowing her nose, that some disturbance—associated with a crackling sound—took place in one or both ears. Three days ago (but not, so far as I could ascertain, until several hours had elapsed since the use of the salt water), she began to suffer from pain in the right ear. Pain rapidly increased in severity. Yesterday five leeches were applied. Temporary relief afforded. To-day pain again severe. Membrana tympani bulging superiorly and posteriorly. Incision, giving escape to but little bloody serum. The following day there was decided swelling of the inner half (especially posteriorly) of the meatus, and tenderness over the mastoid process. Two free incisions through swollen tissues of meatus and Shrapnell's membrane, and free incision of mastoid integuments. Decided relief. Subsequent progress of case toward recovery slow. Perforation in membrana tympani healed on the twenty-fifth day of the disease.

## A CASE OF PROGRESSIVE MUSCULAR ATROPHY RESEMBLING LEAD PARESIS.

BY ALLAN McLANE HAMILTON, M.D.,

ONE OF THE VISITING PHYSICIANS TO EPILEPTIC AND PARALYTIC HOSPITAL, BLACKWELL'S ISLAND, NEW YORK CITY.

SEVERAL months ago Mr. N., a Cuban gentleman, came to me with a letter from his medical adviser, Dr. Findlay, of Havana. The doctor's history of the patient is as follows:—"Mr. N., about eighteen months ago, began to experience a tremor in the fingers and wrist of the right hand, together with muscular debility, which caused some inconvenience in writing and carrying food to his mouth, as well as in other movements of the hand. Having on a single occasion submitted to local faradization of the arm (some ten months ago), the tremor was much subdued, and, as was thought, the fingers and wrist were strengthened. It was not, however, until four months ago that the patient returned to put himself under a regular course of treatment.

"Condition of the patient in July last.—General health good; no signs of cachexia; no antecedents of specific taint; no lead poisoning. Suffered on two or three occasions, at some years' interval, rheumatic pains and neuralgia in the arm and shoulder of the left

side, but never in the *right* side, which is the one now affected. The outer appearance of the right arm showed but little muscular atrophy; the tremor was inconsiderable; the patient could close the hand tightly, but not well grasp larger objects, such as a tumbler, owing to incapacity to maintain the first phalanx of the third, fourth, and fifth fingers extended. The wrist was inclined to drop forwards (in flexion) and outwards.

"On inspection it was found that the *common extensor of the fingers* was considerably weakened, most so in the portion attached to the ring-finger, the weakness being manifested both to voluntary and to electrical contractility. The same condition existed also, though a little less, in the *extensor of the little finger*, and in the *radial extensors*. The contractility was not totally absent, but would vary in degree without apparent cause. The disease continued to progress (notwithstanding treatment), the portions of the *common extensors* losing all excitability to my small Gaiffe's battery, and the extensors of the thumb being also implicated.

"The *left* arm was now examined, and although the patient did not notice any weakness in the hand, some deficiency of electric contractility was observed in the common extensor, especially in the extensor of the ring-finger. The constant current was now used for six weeks without much benefit. The *extensor carpi ulnaris* is now becoming also affected. The patient, however, finds that he can write and perform various acts with the right hand better than before. Within the last week he complains of some pain along the back of the *left forearm* when he has been holding an object in the air, and feels an inclination to relax his grasp." The doctor also gave a history of hereditary trouble which was probably in one case (the patient's uncle) progressive muscular atrophy.

I carefully examined the patient, and found that the right arm was that most affected.

*Motor power.*—The power of extension of the muscles of the right forearm was lost completely, and on the left side the power of extension of the two middle fingers was to some degree impaired. Flexion was perfect.

*Atrophy.*—The following muscles were more or less affected and reduced in size:

Extensor communis digitorum,	} right forearm.
“ minimi digiti,	
“ carpi radialis,	
“ longus pollicis,	
“ carpi ulnaris,	
“ communis of the left.	

*Sensation.*—Slightly impaired on the right side. The teeth of the aesthesiometer were separated by a space of about ten centimetres before two points could be appreciated. This loss was not so great on the under surface of the forearm. There was no history of recent pain either constant or neuralgic, nor were there any dysæsthetic sensations.

No fibrillary contractions were observed. There was a slight tremor in the right hand when voluntary movements were made. Electric contractility to a very slight degree was observed in the extensor communis digitorum when a strong faradic current was applied. The galvanic current also seemed to have some influence upon the weakened muscles. The fingers were covered by small flakes of skin, and the nails were crusted, irregular, and evidently badly nourished. This trophic defect disappeared under the use of the galvanic current.

*Diagnosis.*—In the order I name them I proceeded to dispose of lead paresis, amyotrophic sclerosis,

cerebral paralysis, traumatic paralysis, progressive muscular atrophy.

That it might be lead paresis seemed reasonable at first, because of the loss of electric contractility, the seat of the paralysis, etc.; but when I bore in mind that the trouble was one-sided at first, that there was a subsequent invasion of the muscles of the other arm, that sensibility was also impaired, and that the patient used neither hair-dye nor drank impure water, nor was exposed to the dangers of lead poisoning of any kind, I was forced to abandon this idea. A species of spastic contraction drew down the fingers of the right hand, and there was some *cumulative* tremor, such as characterizes sclerosis (expressed by a gradually increased tremor, aggravated by will control, and terminating in a species of spasm). This at first led me to suppose that there might be some degeneration of the lateral columns, but as the tremor disappeared and there were no other symptoms of such degeneration, and especially as there was atrophy and muscular paralysis, I dismissed this possibility. The loss of electric contractility, and the limited field of the paralysis, excluded cerebral paralysis; and the fact that the patient had never received an injury, and that the affection was beginning to affect the opposite group, negated the theory of traumatic paralysis. All that was left was the diagnosis of progressive muscular atrophy; and the subsequent appearance of fibrillary contractions made me quite sure of my decision. The slow progress of the trouble and its site were, however, doubtful points. The individual had not exercised any particular member, and as he was a man of leisure, there was no trade nor occupation in which constant use of the hands or excessive labor was required, that could account for its origin. The hands preserved their contour; there was no atrophy; no prominent thenar eminences; nothing suggestive of the *main en griffe*. None of the muscles of the back were affected, and the deltoids were of good volume and power. The fact that others in his family had suffered, that the disease began on one side and extended to the other, that fibrillary contractions were present, that subsequently I was enabled to get slight, and afterwards stronger contractions of the paralyzed and atrophied muscles, determined me in my diagnosis of this anomalous case. I call it anomalous, because I have been taught, and my own experience convinces me, that this is a very rare seat of progressive muscular atrophy. Protean as is the malady, I have not seen paralysis of the extensors, as a primary symptom, in any one of the twenty-eight cases of the affection I have met with from time to time.

Roberts\* considers that the disease, in over one-third of all the cases, begins in the hands.

The trophic phenomena, consisting of exfoliation of the epidermis and the malformation of the fingernails, though pointing to an injury of the nerve, are beautiful arguments for the peripheral origin of the disease.

123 EAST THIRTIETH STREET, Feb. 21, 1877.

## ON THE OPEN TREATMENT OF WOUNDS.

By HENRY A. DuBOIS, M.D.,

SAN RAFAEL, CAL.

The success of Lister's antiseptic method of treating wounds naturally gives rise to the question whether there may not be an antiseptic method equally certain, and in which the wound shall be hermetically sealed to the air, and yet open to manipulation. The advan-

\* Wasting Palsy, p. 127.

tages claimed for Lister's method over all others, are the healing of the wound without the formation of the pus, and consequently the avoidance of the dangers of purulent absorption—also the rapidity of healing. The objections urged against it, are the great nicety requisite in its use, the paraphernalia required, and generally its inconvenience in private practice. Especially are these objections valid in country practice. The surgeon cannot always be armed *cap-à-pie* with spray producers, macintosh, gauze, rubber sheeting, carbolized cotton, etc., nor is it pleasant for him to announce his presence in advance by the carbolic acid odors hanging about his person. Yet he must submit to these inconveniences for the good of his patient, if no equally successful mode of procedure can be devised. While making some experiments on disinfectants some months ago, I was called to treat several lacerated and contused wounds, just the class of wounds to give rise to sloughing and to the formation of large quantities of pus. I give two or three cases in illustration:

CASE 1.—Mr. A., *et.* 70, while working a moulding machine had his arm caught, and one of the two knives on the wheel ripped up the arm from the bend of the elbow to the wrist, cutting the radial, ulnar, and interosseous arteries, and rolling and mangling the integuments, while the other knife cut across the pronator radii teres muscle. After securing the arteries I tried to bring the integuments together, but a space of some five inches remained uncovered. I syringed the wound out with tepid water containing one-fortieth of carbolic acid, and with a spatula filled the wound with the hydrocarbon obtained from the evaporation and clarification of petroleum, and sold under the names of vasoline, cosmoline, etc., to which ten grains of salicylic acid had been added to the ounce. This was thickly smeared over the integuments, and the whole covered by lint with a piece of oil-silk over it, and tightly bandaged. The dressing was removed at first twice a day, then once, and afterwards once in two or three days. A line of separation formed on the integuments, and about one-third died and was removed by the scissors; a portion of the white fibrous tissue sloughed and came away also; but what I would call special attention to is, that throughout the treatment there was no odor and no perceptible formation of pus. The dressings were at first soaked with reddish serum, and this gradually lessening in quantity, granulations rapidly sprang up from the bottom of both wounds, and soon they were closed. I first saw this case Sept. 29th. Oct. 17th the wounds were almost entirely healed, and the patient left for the East overland—about nineteen days in all. It must be remembered that one-third of the integuments and a large portion of the white fibrous tissue sloughed, and that the pronator radii teres muscle was cut across and pounded so that its ends could not be united, and a cavity some two inches deep by three wide was left to be filled in.

CASE 2.—B., *et.* 4, while playing, was kicked by a horse. The horse's hoof struck the middle of the forehead obliquely, making a wound extending nearly across the forehead and raising the integuments, muscles, and pericranium, and rolled them over to a point half way to the vertex. The child being thrown over on the ground the wound was filled with dust. After removing this as well as I could, I found portions of the frontal and both parietal bones laid bare. Washing out the wound with water containing one-fortieth of carbolic acid with a syringe, more of the foreign matter was removed, but a good deal remained bruised into the periosteum that could not readily be

gotten out. The wound was now filled with the vasoline ointment, ten grains salicylic acid to the ounce, and the flaps brought as near together as possible, by long pins, and adhesive strips applied over the head, and over all a close fitting skull-cap. I first saw the case on the 10th of the month, and on the 7th of the next month the wound was entirely healed. The bones of the skull remained bare for some time, and as the child was restless it was found difficult to paralyze the action of the occipito-frontalis, which, being divided, tended to keep the edges of the wound apart, otherwise the healing would I think have taken place in half the time.

CASE 3.—C., *et.* 50, was filling a shell, when it exploded, and lacerated and bruised the ball of the thumb, besides more or less injuring one of the fingers. When I saw him the muscles on the inside of the metacarpal region of the thumb looked like a thick clot of blood, with three cuts, extending down nearly to the bone, in which the finger could be laid. Vasoline ointment of the same strength as the above was at once applied, and he was directed to change the dressing twice daily. He presented himself for the first time in about a week, with the wound nearly, but not quite healed. He said that he had not noticed any matter, other than the oozing of a little serum, and that he had been at work some three days at his trade—that of a painter, and had felt no pain in the hand.

I have used this dressing in a number of cases of minor amputations, etc., but the cases above cited are perhaps sufficient to show its general action. I have had no opportunity to apply it in a capital amputation, and I therefore call attention to these substances, *i.e.*, vasoline and salicylic acid in combination, hoping that they may thus receive a more extensive trial than I am able at present to give them. I would add that no precautions are used to exclude germs other than always keeping a thick layer of the vasoline ointment over the wound. After the first washing out with carbolic acid water the wound is not again touched with water. In the case of a major amputation, I should wash out the wound with the carbolic acid water, let it dry for a few moments, and then fill it with one or two ounces of the vasoline ointment, bringing the flaps together in the usual manner, leaving the corners open. Every day I would inject the ointment by means of a syringe—slightly warmed so as to run freely. I am inclined to believe that recovery will be as rapid as when Lister's method is adopted, and that all dangers of purulent absorption will as certainly be guarded against, and if so, certainly it is more available in general practice. There is no odor to the vasoline ointment, none to the wound, and no odor is left on the hands or clothes of the surgeon. In conclusion, I would add that I believe this mode of dressing is particularly adapted to gunshot wounds. The ointment in these cases should be slightly warmed, and introduced daily by means of a syringe, the parts being kept as near as possible in the position that they were in when the wound was received.

I will, with your permission, in a future number of THE MEDICAL RECORD give a brief account of some new uses of vasoline and salicylic acid in other departments of medicine.

ALUMNI ASSOCIATION, MEDICAL DEPARTMENT OF UNIVERSITY OF NEW YORK.—The following officers have been elected for 1877: *President*, James H. Anderson; *Vice-Presidents*, William A. Hammond, John R. Dickson, Josiah Gautier, S. Fleet Speir, J. J. Peterson, Thomas S. Bahan; *Treasurer*, Dixon Varley; *Secretary*, Frederick R. S. Drake.

## PERITYPHLITIS—OPERATION ON THE ELEVENTH DAY—RECOVERY.

By J. C. ADAMS, M.D.,

LAKE CITY, MINN.

Mrs. J. H.; Irish; æt. 40. Mother of eleven children; youngest six years. Jan. 27th ult., rode eight miles on rough road while menstruating. That night she awoke with slight pain in right flank, which continued the succeeding nights. Monday (3d day), assisted in washing. Wednesday, 31st, saw her for the first time. Pulse 90, temp. 100°. Tenderness on deep pressure in right iliac region. No tumor. No tympanitis. Pain only on motion. Bowels moved day before. Suspected nature of disease impending. Prescribed morph. sulph.  $\frac{1}{2}$  gr., every three hours, and warm water dressing.

As the family did not think the case serious I did not visit her again until the evening of Feb. 7th. In the meantime I was daily informed that she was "comfortable, but weak." On the 6th, being told that her bowels had not moved for several days, and that, though she did not vomit nor "bloat," she was greatly troubled with "gagging," I prescribed calomel gr. v., which operated freely, with relief. Feb. 7th, sent for in haste, patient having had a severe chill and complaining of "a burning in her right side." Temp. 104°. Pulse 100, and feeble. Very firm pressure detected a small, deep-seated, ill-defined induration. Point of greatest tenderness one-half inch above, and one inch to the inside of anterior superior spinous process of ilium. Point of greatest dullness the same. This was the uniform result of oft-repeated palpation and percussion. Dr. Vilas, of Lake City, administering chloroform and rendering other valuable assistance, I divided integument, fat, external and internal oblique muscles, and the fibres of transversalis attached to outer third of Poupart's ligament. An incision was made one inch above anterior superior spinous process of the ilium, and parallel with Poupart's ligament, three inches. I was now able to distinctly feel and partly define the induration, but could perceive no fluctuation. Introduced No. 1 aspirator needle, attached to a small syringe, three times into tumor. First and second time towards its borders, each time obtaining a few drops of pus. Third time into point of greatest tenderness and dullness, and withdrew a teaspoonful of fetid pus. I made a one-half inch incision over this point, inserted the end of my finger, and bored through into what felt like a cavity lined by a villous membrane. I did not explore it laterally. *Extremely* fetid pus gushed out in a continuous stream, and continued to ebb with each inspiration while wound was being dressed. The pubic third of wound was closed by suture, and antiseptic poultice applied and continued one day, being frequently changed. After that carbolized oil (3 ij.—Oj.) on lint was substituted. For the first five days a female catheter was daily inserted in the hole through transversalis. For the first week wound was dressed four times daily, every dressing being preceded by a thorough syringing with carbolic solution (fl. ʒ i.—Oj.). Next day after operating (9th) temp. had fallen from 104° to 100°. Pulse from 130 (at time of operation) to 110. Next morning (10th) temp. 98°, pulse 110. Nothing of note occurred until fourth day, when peristaltic action of bowel at base of wound induced a painful dragging sensation which woke her frequently during the night. An enema, producing a free stool, ended this trouble. A deep inspiration at this time induced a similar pain—"stitch in the side." It re-

curred slightly two days later, when bowels moved, and was not again complained of. Suppuration was established in the wound on the third day, and the healing process was continuous. On the eleventh day after operation (the last time I saw patient) the wound was reduced to a mere sinus communicating with central cavity. Was able to sit up while her bed was being made, and functions all normal. Yesterday (22d) her husband told me the wound was almost healed, and that she was fast regaining her usual health. The important points in this case, I believe, are the following: The absence of visible tumor. The reliability of the indications furnished by percussion and palpation. The value of aspiration as a guide to the point of puncture. The evidence of the near approach of death (tem. 104°, pulse 130, and very feeble) preceding rupture of abscess. The speedy subsidence of all dangerous symptoms after operation.

## Reports of Hospitals.

### THE HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

#### NOTES OF PRACTICE AND PECULIARITIES OF TREATMENT.

THE medical wards of this hospital are under the sole charge of Dr. Wm. Pepper, Professor of Clinical Medicine in the University Medical School, and the modes of treatment given below are all peculiarly his own.

#### ACUTE AND CHRONIC RHEUMATISM.

Quite a number of these cases have been under active treatment in the wards during the past winter. Salicylic acid has been used as an antiphlogistic in the reduction of temperature with very marked success. The dose in cases of acute rheumatism is ten grains every two or three hours, given either in powder, or diffused in mucilage of acacia. A very decided reduction of temperature is usually shown in several hours. In chronic rheumatism ten-grain doses are given thrice daily with the same effects. Salicylate of soda has also been used in these chronic cases, but with no very positive results as yet. Salicin has not yet been tried.

#### ACUTE ANGINA.

Salicylic acid acted most admirably in a case of very severe acute angina attended with a great rise in temperature. Ten-grain doses of the acid given at intervals of two or three hours reduced the patient's temperature from 105° to 99° in the space of two days. The fall of temperature, it is needless to say, was permanent.

#### CHRONIC DYSENTERY.

Two obstinate and well-marked cases of this disease have been promptly and permanently cured. In one instance the treatment was by the late Prof. Simon's proposed method, by "gravity injection." Dr. Pepper was the first to make use of this method in this country. The apparatus is simple, consisting of an ordinary funnel with an elastic tube attached some six or eight feet in length. The liquid to be injected is poured into the funnel. The height at which the funnel should be held depends upon the amount of resistance to be overcome, and the quantity of the injection. In the case under consideration a solution of nitrate of silver, varying in strength from eight to ten grains to the quart of water, was introduced into the

bowel with most gratifying results. At first a pint, and later a quart of the solution was introduced once or twice daily, afterwards once in two days. The injection was retained for from five to ten minutes. Its retention gave no pain, with the exception of a slight burning sensation when the stronger solution was injected. The stools became formed and less bloody very soon after the inception of the new treatment, and in three weeks or so the patient was completely convalescent.

The second case refused entirely to improve under this kind of treatment, but yielded completely to a *pure milk diet*. A quarter of a grain of calomel and ten grains of bismuth were given three times a day for the space of two days before beginning the pure milk diet.

[The "gravity injection" has also cured a case of intussusception in a child, completely disengaging the invaginated bowel.]

#### TYPHOID FEVER.

Dr. Pepper's successful treatment in cases of typhoid fever has been the following: Beginning with the second week of the disease, when the abdominal symptoms of pain and diarrhœa have fully set in, one-quarter of a grain of nitrate of silver with one-twelfth of a grain of belladonna, and from one-sixth to one-half of a grain of the watery extract of opium are exhibited in pill form three times a day after meals. Under this treatment diarrhœa and tenderness have diminished, and patients have made very rapid recoveries. In most cases very little stimulus was used. Milk and beef-tea were the only articles proper of food allowed. Quinine was given with other tonics. Fever was reduced by frequent spongings of the skin of the entire body with cool water. When the high fever resisted sponging, cool baths were employed. Dr. Pepper does not by any means approve of indiscriminate bathing in typhoid fever. He holds that the best time for the use of the cold bath is during the early stage—during the first week or ten days in cases where the temperature rises above 103°, and is not controlled by frequent spongings, large doses of quinine (quinine has acted most invaluably as an antiphlogistic both in this and in other diseases), diaphoretics, etc. But when the fever in subsequent stages runs high it is of the nature of a sympathetic fever, largely dependent on the amount of intestinal lesion, and hence cold baths are both less valuable and attended with more risk. Both with the hope of limiting the amount of the specific follicular catarrh of the intestines, and the intention of favorably modifying the secondary sympathetic symptoms, the nitrate of silver has been used. Cold bathing cannot be regarded as a mode of treatment with propriety. It is, however, a very valuable adjunct, applicable in certain emergencies, but its general use in this disease has been overestimated by German writers. In the careful study made in this hospital during the past year, it has also been shown that the temperature laws laid down by Wunderlich and some other statistic writers are far too absolute. These points will be more fully considered in a memoir to be soon published upon the results of observations upon the typhoid fever cases of 1876.

#### PHTHISIS.

The treatment of localized cavities in the lungs by injections of dilute Lugol's solution, originally introduced by Professor Pepper, has been much discussed in the medical press. Further experience with it has confirmed the belief that it is most valuable in some cases as favoring the contraction and

cicatrization of cavities. It is in no case attended with any dangerous consequences. Thus, it does not cause elevation of temperature, hemorrhage, or increase in cough. More recently Lugol's solution has been injected into lung-tissue in cases of incipient phthisis. In one case, *recently discharged from the hospital*, the treatment was pursued nearly every week for a number of months. The disease was arrested, the physical signs disappeared, the general symptoms greatly improved, and the patient was discharged APPARENTLY WELL. In another case, still under treatment, the effects of each injection appear distinctly favorable. Dr. Pepper does not by any means regard the question as having reached a point where positive conclusions can be stated. He contends, however, that it has been shown that this mode of treatment is without danger; that in some cases at least it does good, and that it is deserving of thorough investigation. The probable mode of local action of iodine and other alteratives has been discussed in part previously, and will be made the subject of a memoir at an early date. The strength of the solution used for injection varies from one part of Lugol's solution to five parts of water, all the way up to equal parts of each.

### Progress of Medical Science.

ON THE USE OF WARBURG'S TINCTURE.—Dr. Broadbent, of St. Mary's Hospital, London, claims that he has used Warburg's tincture with great success, believing, indeed, that he has saved life by it in several instances. Its efficacy he attributes to quinine, which, though present in the small proportion of nine and a half grains to the ounce, is aided in its action by powerful aromatics. To render the tincture thoroughly efficient it should be given without dilution, at intervals of two or three hours, during which time nothing should be taken but a little beef-tea or brandy, and this only if required by the state of the patient. The applicability of the remedy is to those cases where there is no organic disease necessarily fatal and where the local inflammation is inadequate to produce the symptoms, but the nervous system is overwhelmed by a poison, as in malignant remittents, or perhaps by pyrexia simply.—*Practitioner*, February, 1877.

ANALYSIS OF ONE HUNDRED AND NINE CASES OF RHEUMATISM, TREATED WITH SALICYLIC ACID AND SALICINE.—Dr. Brown, late house physician at the Boston city hospital, has furnished a tabulated statement of all the cases that were treated in the hospital with salicylic acid or salicine since February 12, 1876, at which time this method was first inaugurated there. Cases of undoubted chronic character are excepted. The average amount of acid taken to produce relief was one hundred and fifty-four grains; the quantity varied from thirty to two hundred and ten grains. The average of the time at which relief was effected was 1.46 + days, varying from three hours to four days. The average time to complete cessation of pain was 2.85 + days, varying from twelve hours to fifteen days. The amount required to produce complete relief from pain and mobility of the joints was 531.22 grains to each patient; in each attack was 343.73 grains. The average time during which the acid was taken by each patient was 6.22 days, varying from one day to thirty-one days.

Two cases died, one from pericarditis and one from cerebral complications. Eighteen cases had one relapse, three had two, and one had five while in the hospital. The universal result of the acid, when

given in full doses, was to cause a fall of the temperature. On the pulse and respiration the effect was less marked: in fact, the pulse often increased for a time, in debilitated subjects. The patients were usually placed upon the treatment by the house physician soon after entrance, ten grains being given hourly while awake. The practice varied from this in some instances. In Dr. Blake's service pills containing three and one-half grains each were made with honey or molasses, and in this form the acid was best taken. The number of cases treated with salicine was too small for instituting comparisons. In three cases of acute rheumatism, with moderate severity, from five to fifteen grains were taken hourly; the average time, to relief was two and one-third days; to complete relief six and one-third days; the average amount taken was three hundred and forty-six and two-third grains. The average time in hospital was thirteen and one-third days. It is thought that salicine deserves a more extended trial.—*Boston Med. and Surg. Journ.*, February 8, 1877.

**A CASE OF LITHOTRITY IN WHICH NITRIC ACID INJECTIONS WERE EMPLOYED.**—In March, 1875, a police officer, aged forty-five, was admitted into the Liverpool Royal Infirmary, under the care of Mr. Harrison. Upon examination, a single stone was found in the bladder; it was rounded and had a diameter of two inches and a quarter. The urine was alkaline and contained pus. After some preliminary treatment, lithotripsy was performed on April 5th, and the crushings were repeated twelve times during April and May. The patient never experienced any unfavorable symptoms, and a good deal of broken-up stone was passed, but as it seemed that fresh phosphatic depositions were taking place almost as fast as the others were removed, Mr. Richardson resolved to use nitric acid injections. On May 27th (two days after a crushing), he had all the urine passed during twenty-four hours collected and examined. Its quantity was sixty ounces, and it contained 74.029 grains of phosphoric acid in the form of alkaline earthy phosphates, and 250.516 grains of phosphoric acid in the form of alkaline phosphates. He then injected into the bladder half a pint of tepid water with two drachms of dilute nitric acid. During the next twenty-four hours seventy-eight ounces of urine were passed, which were found to contain 96.237 grains of phosphoric acid as alkaline earthy phosphates, and 461.94 grains of phosphoric acid as alkaline phosphates. Hence, after the nitric acid treatment, the percentage of alkaline earthy phosphates in the urine was slightly increased, while that of the alkaline phosphates was very considerably increased. The absolute increase of the phosphates was, however, much more marked. On nine subsequent occasions the lithotrite was employed, and on every second or third day afterwards the bladder was injected as before with tepid water and nitric acid. The alkaline phosphates were increased after each injection, and it was also noticed that the fragments passed were more fine triturated than previously. The patient left the infirmary cured on June 21st. The total quantity of broken-up stone collected weighed four drachms. Mr. Richardson thought that the acid stopped at once any further deposition of phosphates, and facilitated the removal of the broken fragments.—*British Medical Journal*, January 6, 1877.

**WHEN IS THE CATHETER TO BE USED FOR HABITUAL RETENTION FROM HYPERTROPHIED PROSTATE?**—In a lecture on this question delivered in the University College Hospital, December, 1876, Sir Henry Thompson stated that, in order to arrive at a judgment in

any particular case, it is necessary to know, first, the amount of "residual urine" habitually present, and, second, the frequency of micturition, particularly at night. In reference to the first point, the physician will of course not always judge from one trial of the catheter. The amount of urine left in the bladder is pretty uniform in most patients, when there is nothing to disturb the function of micturition, such as, for instance, the presence of a stranger, etc. Sir H. Thompson thinks that, when eight ounces always remain behind, the patient should at once commence the daily use of the catheter, but this may be necessary when the quantity is much smaller. It has been laid down as an axiom by some, that so long as the urine is clear, no matter what the quantity retained, no instrument should be employed. A certain amount of *a priori* reasoning may be urged in behalf of such a rule, but it will not bear the test of large experience. It means neither more nor less than waiting for the occurrence of chronic cystitis before we use an instrument. This cystitis is the very condition we wish to avoid, and do mostly avoid by commencing the use of the catheter at a sufficiently early period. In past days, when physicians had only the large metallic catheter at their command, chronic cystitis was a frequent result of catheterism, but it is rarely so nowadays, with the soft, flexible instrument of moderate size, provided it be used at an early period, before considerable accumulation has taken place; the removal of a large quantity being mostly, but not invariably, followed by local and general disturbance. When the residual urine is allowed to reach the quantity of twenty ounces or more, it is seldom that the patient does not suffer rather severely from both chronic cystitis, with purulent urine, and febrile attacks, with resulting debility, whenever the daily use of the catheter has to be commenced. Moreover, at this advanced stage of chronic retention, a slight accident of some kind readily occasions complete, or nearly complete, retention, and then the use of the catheter is imperatively demanded. Under these circumstances, chronic cystitis is almost sure to follow. Hence, in cases of continued and chronic retention, due to slowly advancing hypertrophy of the prostate, the longer the use of the catheter is postponed after the early stage of the malady is passed, the worse will be the symptoms.

The frequency with which the patient passes urine must also be taken into account. It is more important to note whether the patient is disturbed six times in the night or only twice than whether his urine is clear or cloudy, or even whether the residual urine amounts to four ounces or twelve. If he is affected by loss of rest, pass the catheter the last thing at night, and mark the result. If he obtains four or five hours of continuous sleep after the bladder is emptied, he should be taught to pass the catheter himself every night. Moreover, the avoidance of pain and spasm by this treatment makes it sometimes desirable, whatever be the quantity and character of the urine removed. By taking into consideration the different phenomena in each individual case, and giving to each its due importance, a correct judgment can usually be reached without difficulty.—*The Lancet*, January 6, 1877.

**NEW METHOD OF DOUBLE STAINING.**—Drs. Norris and Shakespeare, of Philadelphia, recommend the following solutions as desirable modifications of Merkel formulae: The red-staining fluid contains carmine,  $\frac{3}{4}$  ss.; borax,  $\frac{3}{4}$  ij.; distilled water,  $\frac{3}{4}$  iv. The blue-staining fluid contains indigo-carmine,  $\frac{1}{4}$  ij.; borax,  $\frac{3}{4}$  ij.; distilled water,  $\frac{3}{4}$  iv.—*American Journal of the Medical Sciences*, Jan. 1877.

# THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, March 24, 1877.

## THE NEW YORK HOSPITAL.

AGAIN this old and familiar name is destined to associate itself with deeds of active charity for suffering humanity. After an interval of six years the institution which for a century has been so closely identified with the medical and surgical history of this metropolis, has now a positive entity and permanent abiding-place. The reopening of the new buildings on West Fifteenth and West Sixteenth streets was formally signaled by the tasteful and appropriate address of Prof. Van Buren, setting forth the history, objects, and aim of the hospital, followed by a brilliant reception of the members of the medical profession and a large body of distinguished citizens. In connection with the present re-establishment of the institution a glance at its previous history will, we trust, not be uninteresting.

The charter of the hospital dates back to the reign of George the Third, having been granted on the 13th of June, 1771, by the Earl of Dunmore, Governor and Commander-in-chief of the provinces. The first suggestion relative to the founding of a free infirmary was made by Dr. Samuel Bard, an eminent physician and whole-hearted philanthropist of early New York. Dr. Peter Middleton, in an address delivered November 3, 1769, before King's College (since the American Revolution called Columbia), made the following remarks: "The necessity and usefulness of a public infirmary had been so warmly and pathetically set forth in a discourse delivered by Dr. Samuel Bard,\* at the college commencement in May last, that his Excellency Sir Henry Moore immediately set on foot a subscription for that purpose, to which himself and most of the gentlemen liberally contributed. His

\* Dr. Bard practised for more than fifty years in the city, and was the author of a curious volume on "The Malignant Pleurisy, as it Prevailed on Long Island in 1749." He served the hospital as physician for twenty-three years, from 1774 to 1797, and died at the age of eighty.

Excellency also recommended it in the most pressing manner to the Assembly of the Province as an object worthy of their attention." Farther on the same speaker foreshadowed what the institution was to be, and every one who knows anything of it is willing to acknowledge that it has nobly verified the prophecy:—"As it is to be on the most catholic and unexceptionable plan, it is to be hoped that it will meet with the countenance and encouragement of every compassionate and good member of society, whatever party or denomination he may choose to be distinguished by on other occasions."

It was not until two years after the charter had been granted that the Governors had collected sufficient funds from private individuals and the State to warrant them in purchasing a site. It originally consisted of five acres, which were purchased of Mrs. Barelay and Mr. Rutgers; and the location was considered most suitable for its purpose, on account of its elevated, airy situation, and other rural advantages, not the least among which was the fine view of the Hudson River on the west. The plot nearly comprised what is now the entire square bounded by Duane, Church, and Worth streets, and Broadway, the easterly line running north and south being a little over one hundred feet from New George street, now Broadway. In order to get an entrance from the easterly side, on New George street (which, although at that time being nothing more than an indifferently kept country road, was still the principal thoroughfare), the Governors afterwards purchased a frontage of ninety feet. The other fronts on Broadway were never in the possession of the Society. At the time of which we are writing the grounds in the vicinity were little better than thickly settled farms, the lots not owned by the hospital on the line of the highway being open, save at what is now the corner of Broadway and Worth street, which was occupied by two or three barns used by some of the down-town cartmen. A portion of these can be seen upon the early print of the diplomas of the hospital. New George street at that time was beautifully shaded by sycamores, elms, poplars, chestnuts, and oaks, and was already beginning to be the favorite drive for many of the aristocracy, who, by the way, mostly lived in the town proper, below the present City Hall Park. Only a few good-sized buildings then stood in the district, among which were Old Trinity Church, built in 1696; the Brick Meeting House in Beekman street, built in 1752; and the St. Paul's Episcopal, now on the corner of Broadway and Fulton street, built in 1765. It will then be seen that the hospital grounds were at first fairly out of town, and that the Governors, in making the selection of the site, had an eye to healthfulness and quiet.

The main or central building was commenced in July, 1773, the corner-stone having been laid with appropriate ceremonies by Governor Tryon. On the

night of February, 1775, when nearly completed, the edifice took fire, and before the flames could be arrested it was almost completely destroyed. The loss thus sustained by the Society was so great, that, had not the Legislature come to its relief by a handsome donation, the whole project would have been frustrated. The breaking out, soon after, of the War of Independence arrested the rebuilding of the institution, and during the occupation of the city by the British it was, in its incomplete condition, used as a barracks and military hospital. For a long time after the close of the war the general derangement of affairs in the city prevented the actual completion of the building, and it was not until January, 1791, that its doors were formally opened for the reception of the sick. History tells us that the first lot of patients numbered eighteen, three of whom were surgical. No pains had been spared to make the edifice, as a whole, as complete as the knowledge of architecture at that period would allow, and it was admitted to be the best of its sort, not only on this continent, but in Europe. Everything indoors was made to subserve the best interests of the patients, as regards comfort and cheerfulness; the windows looked out upon well-kept grounds, the walks for the patients were marvels of beauty to outsiders, and during the cold months the wards were enlivened by the comfortable blaze of oak and hickory, in large, old-fashioned, open fire-places.

After the War for Independence, and previous to its formal opening, the hospital, although incomplete, was, nevertheless, used as an infirmary for the townspeople in the vicinity, and occasional lectures were delivered to students of medicine and surgery by the physicians and surgeons of the institution. It also appears that dissections were stealthily carried on about this time, partly upon the bodies of such paupers as had died under treatment, but mostly upon the stolen treasures of Potter's Field and the old Negro Burying Ground. All the care on the part of those interested could not keep these depredations a secret from the people, and the result was eventually the "Doctors' Riot," which took place in 1788—one of the truly memorable occurrences in the early history of the hospital. On the south side of the main building, and from one of the second stories, some one had suspended a partially dissected upper extremity, which, being in full view of a party of boys at play in Duane street, after a while attracted their attention. A cry was raised, "A dead man has been cut up in the hospital, and his arm is hanging out of the window!" Some sailors coming up Duane street from the North River very readily took up the cry, and soon collected a crowd to storm the edifice. Some climbed over the fence, but the main body proceeded to the front entrance. Two or three medical men who were then in the institution fled, but one, a medical student, not being able to do so, crawled up one of

the open fire-places. The crowd entered, and, after destroying chairs, bedding, and other articles of furniture, demanded of such of the authorities as had the courage to remain in the hospital the perpetrators of the outrage. Failing of any satisfaction in this respect, they proceeded to smoke out the poor unfortunate who was found in the chimney. It is needless to say that he was soon forced to descend and capitulate to save his life. It was with great difficulty that the institution was saved from the firebrand; and it was not until two or three days had elapsed, during all of which time the anger of the populace smouldered under the dampening arguments of the city authorities, that the disturbance was effectually quelled. Even at the end of that time the instigators of the riot were determined not to be satisfied until a formal inspection of the hospital was made by a number of prominent and respected citizens.

From time to time the hospital had been increased by additions in the shape of extensions and separate buildings. In 1806 an edifice was erected on Duane street for an insane asylum, and was occupied as such until 1821, when the patients were transferred to the Bloomingdale Asylum. In 1825 the deserted asylum was fitted up for seamen, and rebuilt on a magnificent scale in 1853. In 1841 a large building on Worth street was erected; and in 1850 the interior of the main building was remodeled.

From that time until 1869, the hospital maintained its position on Broadway, and was cherished by the citizens not only as a noble charity, but as a precious landmark of Old New York. Its ivy grown walls, rich lawns, and the noble elms which crowned the main entrance made it an object of admiration for the stranger and one of veneration for the citizen.

It soon became evident by lack of funds for carrying out its objects, that the institution must be removed and the property disposed of. The necessity for such a radical measure was resisted for a long time, but was finally acknowledged. The lawn, elms, and buildings disappeared, and the grounds became occupied in due time with huge stores, closing up everything to the margin of Thomas street, which is on a line and continuous with what was once the avenue to the old Main House.

It would be exceedingly interesting to refer to the many changes which took place in the growth of New York during this period of the existence of the hospital, but space will not permit. We hasten to glance at that portion of its history which is more especially interesting to medical men.

The hospital, since its foundation—a comparatively short time ago—has earned for itself a reputation not inferior to that of any other institution of its kind. The late Professor Joseph M. Smith, in an address delivered in 1855, on the occasion of the inauguration of the "New South Building" of the New York Hospital, in regard to this point, truly said: "There has been

no case admitted into the house warranting and requiring an operation, however formidable, which has not here found a surgeon qualified by his knowledge, his eye, heart, and hand, for its performance. Operations of which there were few or no precedents, and so unpromising in their results as scarcely to justify their performance or repetition, have been executed with a skill that elevated the operator to the level of those enjoying the highest European reputation."

In the small operating theatre at the north of the main house, Dr. Wright Post, in 1813, made the first repetition, with a favorable result, on this side of the Atlantic, of Sir Astley Cooper's operation of ligature of the common carotid, for aneurism; it was in the same theatre, in 1817, that the same gentleman tied the first time, with success, the right subclavian artery, for brachial aneurism; it was here, in 1818, that the late Valentine Mott won his reputation as the first ligator of the arteria innominata; it was here, in 1845, that the late Dr. Kearney Rodgers tied for the first time the left subclavian inside of the scaleni muscles for aneurism; it was here, in 1847, that Buck introduced his operation of scarification, as a means of relief in oedematous laryngitis. Aside from all this, the wards of the hospital have been made famous by the teachings of the late David Hosack, John Watson, John C. Cheesman, Alexander H. Stevens, Edward Miller, John A. Swett, Joseph M. Smith, Thaddeus M. Halstead, and Gurdon Buck, all passed away—but with their names must ever be associated a reverential remembrance.

The new Hospital buildings are admirably situated, and well calculated to serve the purposes for which they have been constructed. As far as equipment is concerned, there is nothing to be desired; in fact, the hospital is furnished so regardless of expense as to amount to actual extravagance; but this may be considered an error on the safe side, especially so far as it may serve as a rebuke to actual parsimony in other institutions. Although arranged with every convenience for the comfort of the patients, and every necessary for the attending staffs, it is a matter for regret that the compulsory economy of ground-space compelled the multiplication of stories. The latter objection, however, may be counterbalanced by the very commendable care taken to overcome all other unsanitary conditions in and about the buildings; in fact, they are as near perfection as they can be under the circumstances. And now that the hospital has once more thrown open its doors to the sick, the best wish we can offer it is that its usefulness and renown for the future may equal, if not excel, that of the past.

#### INSPECTION OF DRUGGISTS' WEIGHTS.

THIS important measure still hangs in the Senate Committee on Public Health, of which the Hon. Wm. N. Emerson, of Rochester, is chairman. If the committee fail to report it, the profession and the public

will know upon whom the responsibility rests. We are assured that when the bill reaches the Assembly the professional members of that body will give the matter their earnest attention.

## Reviews and Notices of Books.

A TEXT-BOOK OF PHYSIOLOGY. By M. FOSTER, M.A. M.D., F.R.S., Prælector of Physiology, and Fellow of Trinity College, Cambridge. London: Macmillan & Co. 1877.

WITHIN the last ten years a great number of text books of physiology have been written, but few deserve attention. Most of these written on the subject of physiology within that period are behind the time. The science of Physiology has entered into an era of positiveness which is as secure as the one upon which mathematical science is founded. The physical methods are used to study physiological problems. This book of Prof. Foster, together with the works of Herman and of Beauvis, are conceived in the new spirit, and commend itself by its completeness and conciseness. Although it cannot be said to contain very much original matter, yet the manner in which the author has dealt with his subjects, and the divisions which he has made between them, constitute no little originality. He has begun his treatise by the study of the blood, taking next the contractile tissues, then the nervous system, and the vascular system, etc. His chapters on muscular contraction are very good, and contain all that not only a student, but a general practitioner could desire. Those topics relative to the nervous system and to the other systems, on which authorities yet differ, he has inserted in smaller text, in order to indicate to the average student that his close attention is solicited only by what is contained in the larger text.

In order to appreciate the immense progress made lately in the study of physiology, let any one compare such a book as this one of Prof. Foster's, or of Prof. Herman's, or of Beauvis', with older works, and he will see such a difference not only in the notions entertained generally, and such a difference in the methods of investigation employed, that the two series of books will appear to treat of two different sciences.

We recommend this treatise to students desirous of gaining some accurate knowledge of physiology, so very necessary to a good physician, and we assure all that it is a very fair work of reference.

DIAGNOSE UND THERAPIE DER KRANKHEITEN DES MENSCHEN, mit zugrundelegung der Lehren und Recepturen der ersten medicinisch-chirurgischen Autoritäten und Anführung von 1,500 Receptformeln im metrischen Gewichte, nebst einem Anhang über Balneologie. Von DR. BERNARD KRAUS, chefredacteur der "Allgemeinen Wiener Medicinischen Zeitung."

THIS work of nearly a thousand pages, by the editor-in-chief of a leading German medical journal, is designed as a compendium of our present knowledge in regard to the diagnosis and treatment of diseases of the human body. Its list of subjects comprises internal diseases, the diseases of women and children, cutaneous and syphilitic affections, diseases of the eye and ear, and surgical diseases, with a description of important operations and their after-treatment. An important feature of the work is the addition to each article of suitable formulae for prescriptions, many of

them taken from those in use by "the first clinical physicians of Europe." Manuals of this kind obviously meet a certain demand, otherwise it is difficult to see why industrious writers like our author should be at the enormous trouble of compiling them. They always remind us, however, of the casual visitor to a library in Philadelphia, who, bewildered by the great number of volumes, inquired whether there wasn't some book that had it all in." To be sure the advance of medical science is so rapid that the majority of our poorly-paid profession find it impossible to keep their libraries abreast of recent work in *special* branches, and manuals upon such subjects must, therefore, be regarded, if not as an unmixed good, at least as a necessary evil. Excellent work in this direction has already been done by our author in his "Compendium of Recent Medical Science," which includes such topics as thermometry, sphygmography, percussion and auscultation, microscopy, electro-therapy, etc. Compendiums of the present character, however, which attempt to deal with nearly the whole of the general practice of medicine and surgery tend to replace more thorough works, and naturally lead to empiricism, to search for a "remedy against a disease," rather than to a careful study of the disease itself. Still, much as we object to the *scope* of the work, we have nothing but praise for the manner in which the author has carried out his design. The pictures of disease, although drawn only in outline, are admirably distinct, while for the thoroughness with which the material is brought up to the most recent stand-point of medical science, the work is unequalled by any of a like character in our own language. For English readers, moreover, the very full list of prescriptions will afford an excellent study of Continental practice, especially in Germany, as well as introduce to their notice many new remedies with new modes of combining them.

**ANNUAL REPORT OF THE MEDICAL SUPERINTENDENT OF THE NEW YORK CITY ASYLUM FOR INSANE, Ward's Island, N. Y., for 1875.**

His annual statistical contribution to periodical literature is accompanied with interesting medical notes and deductions. Dr. Macdonald, for instance, is satisfied that intemperance is responsible for the mental aberration of the patients in that special asylum more than all the other causes put together. His experience is favorable to large doses of hydrate of chloral.

**SIXTEENTH ANNUAL REPORT OF THE ALABAMA INSANE HOSPITAL AT TUSKALOOSA, October, 1876.**

The report, by Dr. P. Bryce, devotes considerable attention to the moral treatment of the insane, and claims particular credit for having introduced into the by-laws such exacting disciplinary measures, bearing on nurses and other employees, such rigid accountability, as no other institution, public or private, of this or any other character, can boast of. Manual restraint is an almost obsolete practice in this hospital.

**ANNUAL REPORT OF THE NORTHERN HOSPITAL FOR THE INSANE, Wisconsin, Sept. 30, 1876.**

The medical superintendent of this institution, Dr. Walter Kempster, is a gentleman who has paid an unusual amount of attention to his specialty in all its ramifications. Much of this report is devoted to a retrospective glance at what has been accomplished or the care and treatment of these unfortunates from the earliest Biblical records down to the present day.

## Reports of Societies.

### NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, March 15, 1877.*

DR. S. S. PURPLE, PRESIDENT, IN THE CHAIR.

#### IS TRACHEOTOMY JUSTIFIABLE IN DIPHThERIC LARYNGITIS?

Dr. CHARLES A. LEALE, in answering the above question, considered diphtheria as a malignant and one of the oldest acute infectious diseases; and one in which there was a tendency to the formation of false membrane upon, in, and beneath the mucous membrane of the air-passages. The formation of the false membrane was preceded by inflammation and followed by ulceration, and the exudation contained a virulent poison, capable of reproducing the same disease by inoculation. It had been maintained by some that tracheotomy should never be performed in cases of diphtheria, in which the false membrane had extended below the bifurcation of the trachea, and when the larynx had become so completely occluded that the patient would die asphyxiated if an opening were not made. Tracheotomy was first successfully performed in 1782, by Dr. John Andree, of London. Bretonneau made his first successful operation in 1825, and Trousseau, in the year 1832, reported his first, which he declared was the third successful tracheotomy after the disease had invaded the larynx.

From 1782 to 1844 the histories of 219 cases, with 40 cures, were collected by M. P. Jousset. Dr. Vose, of New York, had collected and reported 1,249 cases of tracheotomy, with 249 recoveries.

Dr. Leale then reported a case of diphtheria in which recovery followed tracheotomy, performed after the false membrane had filled the larynx, extended to the small bronchi, also down the pharynx, œsophagus, and into the stomach. The child, prior to the operation, was profoundly asphyxiated, and before the tube could be inserted with advantage, large masses of the exudate were removed through the opening by means of long, narrow elbow forceps, carried down to the bifurcation of the trachea. Before the tube was inserted, semi-liquid purulent matter was drained out while the child was held by the pelvis, with the head downwards. It became necessary to resort to artificial respiration to restore the child, and it was continued half an hour before breathing was established sufficiently to justify reinsertion of the tube. The extremely dangerous symptoms were prolonged; symptoms of septicæmia were developed; ulcerations and hemorrhages from the wound occurred; nephritis and general anasarca followed; large pieces of false membrane were discharged from the bowels, and from their size and thickness it was believed they were formed within the alimentary canal; aphonia was present; but after a tedious convalescence complete recovery took place, with restoration of the voice.

The patient was a boy, æt. 2 years 11 months. At the time of the operation he was sinking rapidly; the glands of the neck were enlarged, the face œdematous and cyanotic, and there was great difficulty in breathing. Emetics had been administered, steam had been constantly inhaled, several pieces of membrane had been thrown off, but no relief followed. The intervals between the short spasmodic efforts at inspiration were lengthening rapidly. The operation

was performed as low as the upper border of the manubrium, and with but very slight loss of blood. A few minutes after an insertion of the tube, about an hour after the operation, a piece of membrane could be heard flapping against it. The tube was removed, and, after several efforts, the piece was grasped and removed, when it was seen to be about two inches in length, and branched at the lower extremity, showing that it had extended to the bifurcation of some of the smaller bronchi. The tube was then reinserted, a few drops of brandy and water given as often as the child could swallow, and after two hours the breathing became less labored, and the cyanosis less marked. Steam was constantly generated in the room, and the temperature maintained at 98° F. The false membrane, examined within fifteen minutes from the time of expulsion, contained cocco-bacteria.

The first day after the operation the inner tube was removed every half hour and cleansed.

*Second Day.*—Pulse 120, R. 35. No air passed through larynx.

*Third Day.*—Pulse 135, R. 60. Hemorrhage from erosion about the wound. Profuse expectoration through the tube. Urine contained albumen in large quantities, epithelial casts, and living bacteria. Evening—Pulse at 7 o'clock, 144, R. 62, T. 106 F. At 9 p.m.—Pulse 135, R. 60, T. 105 F. Tube permanently removed on account of erosions and hemorrhage. The bleeding and gangrenous parts, and the surface of the external wound, were touched with pure nitric acid.

*Fourth Day.*—P. 150, R. 60, T. 105 F. Entire surface of the body covered with herpes. Profuse diarrhoea, with discharge of large quantities of false membrane.

*Fifth Day.*—P. 130, R. 28, T. 102½°. Wound in the neck covered with exudation, which reformed as soon as removed by suppuration.

*Sixth Day.*—P. 140, R. 62, T. 105½ F. Unable to breathe through larynx. Some tendency to closure of wound; momentary dilatation by means of piece of sponge.

*Seventh Day.*—No apparent indication for reinserting the tube. From the 7th to the 10th day pulse, temperature, and respiration were alarming. On the eleventh day symptoms much improved, and from that date convalescence went on very favorably, and on the twenty-second day after the operation the patient was well enough to call upon Dr. Leale at his office.

From the time of the operation until recovery was complete no medicine was given. His diet at first was milk, bread, and water, as much as he desired, and, after appetite began to return, any easily digested nutritious food was allowed. The room was kept filled with steam, and the temperature maintained at 98° F. for two weeks.

#### SIMPLE INFLAMMATORY NON-MALIGNANT AFFECTION OF THE LARYNX—TRACHEOTOMY—SPEEDY RECOVERY.

A healthy man, *et.* 28 years, got chilled and was attacked with difficult breathing and other croupy symptoms, Jan. 30th. He was relieved by the use of steam, emetics, and gargle. The following day there were marked symptoms of œdema glottidis, and Buck's method of scarification was resorted to with relief. On the third day the symptoms of œdema were renewed, and were not relived by steam, scarification, etc. On the fourth night Dr. Leale was called, but upon arrival was met by the attending physician and clergyman, who said the man had ceased to breathe. The heart, however, was found to be beating. Dr.

Leale quickly opened the trachea, inserted a tube and began artificial respiration, and at the end of an hour had the satisfaction of seeing his patient breathe independently. Within forty-eight hours the œdema of the glottis had so subsided that the tube was removed, the wound healed kindly, the white exudation in the larynx exfoliated or was absorbed, and the man was able to be at work within ten days from the time of the attack. The case proved, not only the justifiableness of tracheotomy in certain cases of laryngeal affections aside from diphtheria but its imperative demand.

#### OPINIONS REGARDING THE JUSTIFIABLENESS OF TRACHEOTOMY.

DR. SAMUEL D. GROSS states that the operation is seldom successful, either in diphtheria or croup, but that it is justifiable, because it affords the patient a more easy mode of death than by asphyxia.

DR. F. H. HAMILTON believes that tracheotomy in diphtheria, under well-defined conditions, is no longer a question of doubt, but is justifiable.

OERTEL believes that tracheotomy in diphtheria is indicated only when the local affection preponderates.

DR. MEIGS, in his article on pseudo-membranous laryngitis, gives the opinion that tracheotomy is a justifiable operation.

DR. CHARLES WEST, of London, regards the operation as scarcely a justifiable proceeding in cases of croup, and that when the larynx becomes involved in diphtheria the case is utterly hopeless.

DR. J. LEWIS SMITH states that when the respiration becomes so embarrassed that lividity occurs the propriety of tracheotomy becomes a serious consideration, and that only in exceptional cases will it save life, but it renders death more easy.

VOGEL believes that the operation in diphtheria should be discouraged, because the physician has to deal with a general disease, of which the laryngeal symptoms are only local manifestations.

NIEMEYER is of the opinion that the operation, if it is to succeed—and he thinks it rarely does—should not be deferred too long in treatment of the laryngitis, either croup or diphtheria.

DR. COHEN makes the statement, based upon the published records of more than five thousand cases, that the operation is indicated whenever death from suffocation cannot be averted by any other means.

DR. E. W. BARCLAY, St. George's Hospital, London, regards this operation as justifiable, but to be successful it must be performed early.

BOUCHUT believes that when fits of suffocation are developed in croup, the case should at once be treated by tracheotomy.

DR. AUSTIN FLINT believes that the justifiableness of tracheotomy is based upon the affirmative answer to the question, Are lives ever saved by it?

TROUSSEAU believes that the operation should be tried, no matter what degree of asphyxia may have been reached; there is a chance of success, provided the local lesion constitutes the chief danger of the disease.

A FRENCH surgeon had operated forty times and lost every patient.

MR. SPENCE, in an address before the British Medical Association, claims that the practitioner should not be discouraged by reason of repeated failures to save life by tracheotomy.

In three instances in which Dr. Leale had been called upon to perform tracheotomy in diphtheria he had declined to operate, and two of the patients had recovered.

The French have reported a larger proportion of recoveries after tracheotomy than have either English or German writers.

Dr. Leale maintained that the operation should not be performed early in the disease, inasmuch as it had been seen that an equal proportion of desperate cases recovered without it, through the influence of approved medication and continuous inhalation of steam. It is to be acknowledged that when the membrane inside the smaller bronchi and cyanosis was marked, only a small proportion recovered; but it was also remembered that the operation itself might add to the gravity of the case by causing deep-seated ulcerations and hemorrhages, and establishing new foci of irritation, infection, and gangrene.

#### CONCLUSION.

The conclusion reached was that tracheotomy was a justifiable operation, in undoubted cases of diphtheritic laryngitis, only when death was impending in consequence of the occlusion of the air-passages. Recovery might follow notwithstanding profound systemic infection, and, under those circumstances, where there was the slightest opportunity to gain time in which to overcome the effects of the poison, the operation, thus removing one obstacle to recovery, was not performing our last remaining duty.

Dr. L. A. SAYRE remarked that he had performed tracheotomy eight times, and that five of his patients were yet living. One death occurred from hemorrhage produced by a defective tube; the tube lacerated an artery, and death resulted from exhaustion due to the hemorrhage. The case could not be fairly reckoned against the operation. Whether the cases were such as legitimately belonged in the class to which Dr. Leale had restricted his paper, the doctor was unable to say positively; he had regarded them as cases of croup.

Dr. Sayre believed that his good results had been largely due to the beneficial influence of continuous inhalation of steam for several days after the obstruction had been removed by the operation. He had seen several cases of croup in which death from suffocation seemed imminent, but which had recovered under the rigorous and constant application of steam. Fill a room with the vapor of hot water and make the patient breathe it for days. Several cases were related. Dr. Sayre thought that the case related by Dr. Leale established the propriety of the operation beyond question.

Dr. GARRISH recommended the use of steam after the operation. Of the justifiableness of the operation he was fully convinced, and thought Dr. Leale's cases had done much to establish such position, whatever opinion may have previously been entertained by the profession.

Dr. J. C. PETERS presented the following statistics taken from Sanne's work, published in 1877. Several series of cases from France were given, namely:— Out of 60 operations there were 18 recoveries; 128 operations and 29 recoveries; 212 operations and 40 recoveries; 169 operations and 57 recoveries. In Portugal there had been 21 recoveries after 59 operations for tracheotomy; in Belgium 8 recoveries had followed 35 operations; in Germany, out of 912 operations, there had been 165 recoveries; in Austria, 79 operations with 28 recoveries; in Prussia, 6 operations with 2 recoveries; in Switzerland, 185 operations with 60 recoveries; in London, 20 operations with 4 recoveries; in America, 325 operations with 84 recoveries.

Dr. Peters was of the opinion that Dr. Leale's case went further towards proving that the operation of

tracheotomy was justifiable in diphtheria than any that had yet been brought forward.

Dr. BEVERLEY ROBINSON remarked that the great success of the French in the operation was no doubt due in a very great measure, if not entirely, to the fact that they were the most expert operators, and that the operation was performed early. He further suggested that whenever tracheotomy was performed, the tracheal fistule should be covered with gauze for the purpose of preventing the entrance of atmospheric germs. The doctor took issue with Dr. Sayre in reference to the use of steam, on the ground that when tracheotomy became necessary, the patient was in a more or less cyanotic condition, the operation was performed for the purpose of affording more perfect oxygenation of the blood, and that steam prevented rather than favored such result. For, in an atmosphere charged with steam, the proportion of oxygen was very much diminished, hence the patient was by so much deprived of the very element which we wished to have in the blood. It was not to be expected that as good results would be obtained if operating in the cold fog of London as in the dry atmosphere of New York.

Dr. PEASLEE remarked that the case reported by Dr. Leale rendered the operation justifiable. Not only that, but it must be remembered that the fact that Dr. Leale believed it to be justifiable contributed in a great measure to its success. If Dr. Leale had been in the same frame of mind as the surgeon to whom he had made reference, and who had lost forty patients after the performance of tracheotomy, probably his own patient would not have recovered, for it would seem that if less had been done the case would have inevitably terminated fatally.

With reference to the gauze which should cover the fistulous opening, as suggested by Dr. Robinson, it was to be remarked that the germs spoken of were invisible, while the openings in the gauze were visible to the naked eye. The germs, therefore, could readily pass through the openings in the gauze, and, besides, the gauze would act as an obstruction to the egress of the poisonous material which we desired to eliminate.

With regard to the influence of steam it was very easy to theorize, but there were certain facts, relating to cases in which it had been employed, that could not be so easily ignored. It was well known that steam had benefited many cases, and he would explain its beneficial influence by the fact that, coming in contact with mucous passages, the foreign substance was softened and put into a condition which increased the chances for its easy removal. It was expectorated, we would say, and then we had got rid of the primary cause which prevented proper aeration of the blood. Dr. Peaslee was willing to admit that an atmosphere laden with steam contained a diminished proportion of oxygen, but at the same time maintained that the use of steam so facilitated the entrance of air that a greater amount was taken into the lungs, and, therefore, a correspondingly larger proportion of oxygen. He was, therefore, of the opinion that steam had a practical value in the class of cases under consideration.

With regard to the cold fog of London, to which Dr. Robinson had made reference, it was a noteworthy fact that the mucous membrane of the air-passages of many persons was so sensitive there was a constant hacking cough while in a dry atmosphere, but when in a moist atmosphere the same individuals were comparatively free from any such annoyance.

Dr. SAYRE remarked that no one in New York would

think of operating in *cold*, foggy London, for it was heat as well as moisture that was demanded.

Dr. HANKS called attention to one noticeable fact in Dr. Leale's case, namely, it illustrated that a severe case of diphtheria might recover without medication. It was very commonly recommended that large doses of quinine should be administered to reduce temperature, and a variety of other remedies employed, both for local and constitutional effect, but in the case reported the child recovered without the aid of any medicinal agents. In his experience pseudo-membranous croup in this city was an exceedingly rare disease. Not long since he was called to see a child, and made the diagnosis of membranous croup, and was unable to recognize any general systemic infection. Within one week another child in the same house was taken ill and presented unmistakable signs of diphtheria. Since that time he had seen several like instances, and had come to regard his diagnosis of membranous croup as incorrect, and believed the original cases were true diphtheria.

Dr. BLUMENTHAL regarded Dr. Leale's case as one in which the operation was justifiable, but desired to call the attention of the Academy to two cases. One was the case of a child which had become very cyanotic and was apparently in an extremely dangerous condition, so much so that a surgeon had been called to perform tracheotomy. Dr. B. preferred to employ other measures for the relief of the patient, and the operation was postponed one hour. At the end of that time the child was no worse, and the operation was postponed three hours, and by the end of that time the patient had revived sufficiently to encourage the doctor to go on without an operation. The child recovered. The second case was similar, and both illustrated the fact that cases recovered without tracheotomy, even after the most urgent symptoms had been developed.

The Academy then adjourned.

#### SURGICAL SECTION.

*Stated Meeting, March 13, 1877.*

Dr. STEPHEN SMITH, CHAIRMAN.

#### GALVANO-CAUTERY IN SURGERY.

THE discussion was opened by Dr. H. G. PIFFARD, who reviewed the history of actual cautery down to the year 1850, when Middledorf added a new element—namely, the galvanic current. The subject was then studied under three heads: 1, means for generating; 2, means for maintaining; and 3, means for controlling the heat. Under the first heading reference was made to the old methods of generating heat by means of coals applied to the surface, the burning of different substances, such as varieties of wood, cotton, linen, etc., etc., upon the surface to be cauterized, and the use of different metals, such as iron, silver, bronze, and gold. It had been supposed that different kinds of wood and different metals possessed distinct virtues, and a refinement in their use had been carried so far as to recommend certain articles for certain diseases. The introduction of the galvanic current afforded a means for generating heat, the batteries had been so improved as to give a ready means for maintaining it, and ingenious devices had placed the heat under the immediate control of the hand by which the application was made. An interesting description was given of the various batteries that had been devised and the apparent advantages which some possessed over others.

#### THE DEGREE OF HEAT REQUIRED.

Dr. Piffard then gave a practical review of the effect produced by different degrees of heat. For example, boiling water was a cautery, but the ulcer which followed its use was slow in healing, and the cicatrix showed a remarkable tendency to contract. The red heat cauterized, but it destroyed the tissues to a considerable depth, and disagreeable slough followed. If, however, the actual cautery or galvanic cautery was employed as a hæmostatic, the red heat was required, because it coagulated the blood in the vessels; and in operations by means of the galvanic cautery the coagulation preceded the knife, hence no hemorrhage followed.

The white heat destroyed the integument only in which it was applied, and did not penetrate the tissues beneath. The slough separated rapidly, if the heat was applied a sufficient length of time to heat the slough at all, and the ulcer remaining healed quickly. The reason why the deeper tissues remained unaffected was because they were protected by the carbonized surface overlying them. The white heat permitted hemorrhage as much as did the cold knife.

Dr. L. A. SAYRE objected to the *gas cautery*, now in quite common use, on the ground that the screen which had been devised to protect the surface as well as prevent the noise of the flame was very liable to get injured, and so permit an intensely painful vesication all around the point at which the application of the platinum cup had been made. The doctor, therefore, preferred Pacquelin's apparatus.

Dr. DAWSON referred to the fact, too frequently overlooked, that in order to prevent hemorrhage when using the galvano-cautery knife, the heat must travel more rapidly than the knife itself.

#### ANÆSTHETICS.

Dr. F. N. OTIS exhibited Clover's apparatus for administering ether, and remarked that it had given him the best satisfaction of any apparatus he had ever employed, for anæsthesia was readily produced without struggle upon the part of the patient. It could be used for the administration of laughing-gas without producing any of that dreadfully suffocative appearance so commonly attending its use by the methods usually employed. He thought well of prefacing the ether by the use of a moderate amount of nitrous oxide.

Dr. L. A. SAYRE objected to the use of ether because of the struggling on the part of the patient as well as the slowness of its action. He had always employed chloroform, had never had any accident attend its use, and believed that safety depended upon administering it in a peculiar manner. His method was to place five drops, at most ten, in some convenient receptacle by means of which *all* atmospheric air could be excluded from the mouth and nose of the patient. If *all* atmospheric air was excluded such small quantity would quickly and safely produce anæsthesia. If unpleasant symptoms were developed, artificial respiration would keep the patient alive until the effect from such small quantity of chloroform had passed away; whereas when alarming symptoms developed after the patient had been inhaling the *diluted* gas for some time, it was not easy and perhaps impossible to resuscitate him. Used in that manner a pound of chloroform would last him a year.

Dr. OTIS.—It would last me ten years.

On motion made by Dr. Sayre, Dr. Piffard was requested to prepare a report on the galvano-cautery to be submitted to the Academy. The Section then adjourned.

ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from March 11 to March 17, 1877.*

GREENLEAF, C. R., Surgeon. Assigned to temporary duty in the office of the Medical Director of the department. S. O. 40, Dept. of the Gulf, March 6, 1877.

SKINNER, S. O., Asst. Surgeon. Assigned to duty Fort Johnston, N. C. S. O. 49, Dept. of the South, March 13, 1877.

Correspondence.

CROUP AND DIPHThERIA.

TO THE EDITOR OF THE MEDICAL RECORD.

DR.—I have been much interested in reading the discussion, as published in the RECORD, relative to the duality of the two forms of laryngitis, as observed in what we, in the country, call croup proper and diphtheritic croup. So far as my experience goes, it having been principally confined to an extensive epidemic of diphtheria lasting eighteen months, together with many other cases in my own and in that of the practice of others, I cannot imagine how any one can arrive at any other conclusions than those of Professors Flint and Smith. In Central New York, I think, there is but one opinion among the members of the profession, and that is, that they are essentially two distinct diseases.

Without desiring to enter into a purely scientific discussion of the matter, I will briefly make a few statements. In a practice of thirty-four years, in the same locality, I have only seen six or seven cases of what I call pseudo-membranous croup (living in a malarious district); whereas in the eighteen months spoken of heretofore—during an epidemic of diphtheria—I saw *twenty-eight cases* of what I then and now termed diphtheritic croup. Occasionally, since that time, I have seen a few cases of diphtheria, with few terminating fatally in diphtheritic croup. In a few fatal cases of pseudo membranous croup (four in number), death occurred by apnoea, whereas the termination in *every one* of my cases of diphtheria, croup was by death, and that by asthenia.

Right here am I reminded of a remark once made to me by a very clever and intelligent old practitioner, and one which I *fully endorsed*, while speaking upon the difference in the two forms of croup, which was his. Said he: "When I have a case of croup, and it recovers, I know it was *not* diphtheritic croup, for *very one* of the latter dies."

As to the locality of the exudation, with only one exception, I always observed it first upon the uvula, tonsils, and fauces, while the reverse was the case in any cases of pseudo-membranous croup.

I frequently saw cases of the former complicated with enlarged lymphatic glands and hemorrhages, and one case of paraplegia, and met with nothing of the kind in my cases of pseudo-membranous croup. In diphtheria, without the laryngeal symptoms, I saw not a few cases of paralysis of the muscles connected with deglutition and speech. I well remember one case where the patient, while apparently convalescing, and while walking across the room, suddenly fell, and it was ascertained that both lower extremities were paralyzed, with the bladder somewhat involved. In a short time the same diseased action extended to the

muscles concerned in swallowing and in speech. She could neither swallow nor express her wants except by motions and writing. For weeks this condition of things continued, and eventuated in perfect recovery.

I see that Dr. Jacobi says, that the reason why cases of pseudo-membranous croup are not complicated with paralysis, is "because they do not live long enough." While I entertain a high opinion of the doctor's attainments, I desire to briefly relate the following case. I was called to see a little boy, five years old, during the epidemic of which I have heretofore spoken, who had been ill *six hours* with diphtheria, and ascertained upon my arrival that the alarm was "owing to his having become croupy an hour before." Within *twelve hours* of the invasion of the disease, and while suffering from the most distressing dyspnoea I have ever witnessed, he rose in his crib, and fell over upon the floor *completely paraplegic*. He lived twenty-four hours after that, and died, not having regained any control over the lower limbs. Without farther remarks, I will bring this unscientific paper to a close.

D. COLVIN, M.D.

CLYDE, WAYNE Co., March 15, 1877.

Medical Items and News.

PRESBYTERIAN HOSPITAL, N. Y.—Dr. George F. Strady has been appointed Attending Surgeon of this institution, to fill the vacancy occasioned by the death of Dr. Gurdon Buck.

CONTAGIOUS DISEASES.—Comparative statement of cases of Contagious Disease reported to the Sanitary Bureau, Health Department, for the two weeks ending March 17, 1877.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro Spinal Meningitis.	Measles.	Diphtheria.	Small-pox.

THE NEW YORK HOSPITAL.—The formal opening of the New York Hospital was celebrated last evening by an address by Dr. Van Buren, at Chickering Hall, and a reception at the hospital building in West Fifteenth Street. At the hall, the platform was occupied by the Governors of the institution and other distinguished guests, including Secretary David Colden Murray, Treasurer William H. Macy, Frederick A. Conkling, Nathaniel P. Bailey, Sheppard Gaudy, Robert E. Livingston, Jackson S. Shultz, George Cabot Ward, William B. Hoffman, Edward S. Jaffray, Merritt Trimble, Henry J. Davison, Theodoros B. Woolsey, William M. Halstead, Herman R. Lewy, Dr. James P. Gray, of Utica; President Daniel G. Gilman, of the Medical University of Baltimore; Dr. King, of the same institution, and others. Vice-President Beckman presided, and introduced Prof. William H. Van Buren, who delivered an address descriptive of the past history of the institution and the various improvements which modern science has introduced into the hospital systems of Europe and America. The Professor combated the idea that city hospitals to be useful must be located in the suburbs. It was undoubtedly true that the fresh air of the suburbs and

the pavilion system had a favorable effect on the general health of patients, but the present demand was for institutions that could care for the sick and wounded in the heart of the city. In many of the large towns of Great Britain and Ireland the authorities, instead of removing all the great hospitals to the environs, had made large and magnificent additions to existing institutions; among others, to Guy's and St. Bartholomew's Hospitals, in London, and the Royal Infirmary, in Edinburgh, all of which were in the centres of crowded populations. The criticisms which had been urged against city hospitals could be as well urged against cities themselves, and as long as the tendency of popular aggregation was toward the cities, so long central hospitals in the heart of the populous districts would be necessary.

At the close of the address the audience adjourned to the hospital in Fifteenth Street, where a reception was held by the Governors and Board of Officers. The entire building was illuminated and thrown open to the guests, who expressed themselves highly pleased with the result of their inspection.

The hospital proper is on West Fifteenth Street, a few steps from Fifth Avenue, and has a frontage of one hundred and seventy-five feet on that street. Immediately in the rear, and fronting on West Sixteenth Street, stands the old Thorne mansion, which also belongs to the hospital, and is connected with it by handsome passageways. The Thorne mansion will be used for offices, and the general administration of the affairs of the hospital. It contains a medical library of 13,000 volumes, besides the museum and the pathological cabinet. A portion of this building will be set apart as a training-school for nurses.

The hospital building is seven stories in height, two of which are in the Mansard roof. The material of which it is constructed is pressed brick, handsomely trimmed with gray sandstone. The structure is pronounced to be absolutely fire-proof, and will not be insured. The only wood employed in its construction is in the doors. The flooring throughout is composed of tiles laid in cement on iron beams. The partitions are of iron and sand, with iron lathing. The wards, private rooms for patients, physicians, and attendants, and all other portions of the building are thoroughly lighted and ventilated, especial pains having been taken to admit the sun's rays at all hours of the day. Heat will be furnished by steam. Two elevators are provided to facilitate ascent and descent. The water supply is partly from the Croton aqueduct, and partly from an artesian well sunk in the yard, and is abundant for all purposes. The plastering and flooring are of non-absorbent material, and it is claimed will not retain the noxious gases emitted from persons afflicted with contagious diseases, thus obviating the causes of complaint so frequently made against similar institutions. The hospital has a capacity for the accommodation of two hundred patients and sixty attendants. An ambulance service is provided which will be subject to call from the police stations. The Hospital Society is the owner of the ground and buildings in fee simple, the cost of which, including furniture, is \$900,000. The Board of Governors have appointed the following medical staff for the ensuing year: Medical Superintendent in charge, Dr. Francis M. Weld; Consulting Surgeons, Drs. Willard Parker, Alfred C. Post, and William H. Van Buren; Attending Physicians, Drs. William H. Draper, Thomas F. Cook, Charles B. Hackley, James W. McLane, Gouverneur M. Smith, and Woolsey Johnson; Attending Surgeons, Drs. Charles M. Allin, George A. Peters, Robert F. Weir, Thomas F. Markoe, and Henry B.

Sands; House Surgeons, Drs. C. H. Wright, Holt C. Wilson, and S. S. Kahn.

**THE METRIC SYSTEM IN NEW JERSEY.**—The District Medical Society for the County of Hudson, J. J., at the regular meeting held on March 6th, unanimously agreed to a resolution which recommends the use of the metric system in prescribing.

**THE LATE DR. GURDON BUCK.**—At a meeting of the Medical Board of the Roosevelt Hospital, held on March 7, 1877, the following resolutions were unanimously adopted:

*Whereas*, The recent death of Dr. Gurdon Buck, the Senior Consulting Surgeon of the Hospital, though not unexpected, severs a connection of many year duration to most of his colleagues; therefore, be it

*Resolved*, That we tender to the family our earnest sympathy with them in the great affliction which has come upon them, and also that we express, in this imperfect way, our appreciation of the high professional aims, the life-long devotion, and the disinterested benevolence shown by our late associate in his distinguished career of nearly half a century.

*Resolved*, That the Secretary incorporate in the minutes of the board the preceding preamble and resolutions, and publish the same in the medical journals of this city.

T. M. MARKOE, *President*.

ROBT. WATTS, *Secretary*.

**THE ALUMNI PRIZE COMMITTEE OF THE COLLEGE OF PHYSICIANS AND SURGEONS** for the coming year composed of the following gentlemen: Dr. Ellsworth Eliot, Dr. Charles McBurney, Jr., Dr. Frank P. Kinnicutt.

**SANITARY ASPECTS OF THE WAR IN THE EAST.**—Speaking of the possibility of war between Russia and Turkey, the *Lancet* says:—"The two great natural obstacles in the path of the Russians would be the Danube and the Balkans, and, if the Turks retained command of the sea, Varna would be for them a most important position.

"Apart, however, from all military difficulties, there are very grave ones on the score of climate and disease. Very much will of course depend upon the character of the season, upon the duration of the campaign, and its successful progress, but it must never be forgotten that the valleys of the Danube and its tributaries are the homes of endemic diseases, of malarious disease, agues, dysentery, and severe and exhausting fevers, and that in the medical history of all the campaigns against the Ottoman power disease has played a formidable part. Bulgaria is not so marshy near the Danube as Roumania. The climate of Roumania, on the whole, be regarded as good, but it is subject to extreme changes of temperature—hot by day, and cold at night—and it is owing to these alternations together with the miasma arising from the swamps in the vicinity of the Danube and its affluents, that pernicious aguish fevers are prevalent. It is scarcely probable that an army in the field would escape without much inefficiency from sickness—such as fever, diarrhoea, and dysentery, possibly cholera, to which other diseases might be superadded or not, according to the nature and adequacy of all the preparations and arrangements, or the reverse. The success of an expedition will greatly hinge on supplies of good and sufficient clothing to protect against nocturnal cold and a rapid advance. The Russians in 1828 suffered terribly from disease, and the losses among our own troops at Varna, immediately before the Crimean war, from cholera, diarrhoea, and fever, were considerable."

## Original Lectures.

## THE TREATMENT OF ROTARY-LATERAL CURVATURE OF THE SPINE.

BEING REMARKS MADE BEFORE THE SURGICAL SECTION OF THE NEW YORK ACADEMY OF MEDICINE, MARCH 23d, 1877.

By LEWIS A. SAYRE, M.D.,  
NEW YORK.

A NATURAL introduction to the subject for my remarks this evening is a reference to the cause of the rotation in lateral curvature of the spine. In regard to this point I can do no better than adopt the explanation given by Dr. A. B. Judson in a paper read before the New York Academy of Medicine, April 6, 1876, which I take the liberty to quote:

"The distinguishing feature of the explanation of rotation here proposed is the recognition of the fact heretofore overlooked, so far as I am aware, that the posterior portion of the vertebral column, being a part of the dorsal parietes of the chest and abdomen, is confined in the median plane of the trunk, while the anterior portion of the column, projecting into the thoracic and abdominal cavities, and devoid of lateral attachment, is at liberty to, and physiologically does, move to the right and left of the median line.

"In lateral curvature would not a degree of relief be afforded by a similar application (referring to Pott's disease) of antero-posterior force, by which a part of the weight would be transferred to the posterior portion of the spinal column, which is prevented by its muscular and fibrous attachments from deviating far from its normal position?"

To the question asked by Dr. Judson, I give an affirmative answer, with the following qualification, namely: that the superincumbent weight should be removed from the bodies of the vertebrae entirely and be transferred, not to the posterior and comparatively immovable portion alone, but to the irregularities of surface upon the entire trunk. I believe that such indication is fulfilled, to a very great extent at least, by the plaster-of-Paris jacket.

## REMOVING THE SUPERINCUMBENT WEIGHT.

I regard it as one of the great essentials for the restoration of the bodies of the vertebrae to their normal position that the superincumbent weight should be removed. Unless this is done all springs and braces are unavailing, so far as radical cure is concerned. Not only that, but they are to be regarded as injurious, even as a temporary treatment: first, because, as a rule, they are not worn with any sort of comfort; and second, they multiply the curves without straightening the column. The instant the spinal column can be made straight that instant the rotary-lateral curvature is removed. For the milder cases, those in which there is simply a deficiency in muscular activity, some light elastic support which will serve as a reminder to the patients that by their own will they are to bring the muscles into action, together with a proper course of gymnastics, might, perhaps, effect a radical cure. But when the osseous structure of the spinal column has become involved, it is my opinion that all the braces and other instruments which have been devised for the cure of this deformity are of no practical value whatever.

## SELF-SUSPENSION.

It seems that Dr. Mitchell, of Philadelphia (Dr. Sir Mitchell's father), many years ago, taught that

the proper method of treating lateral curvature of the spine was to cause the children to suspend themselves several times daily, maintaining the position a few minutes each time. The method fell into disuse until revived by Dr. Benjamin Lee, of Philadelphia, who continued to employ it, but failed to give due prominence to its worth.

## SUSPENSION BY AID OF APPARATUS.

As a substitute for the usual method of suspension by the arms I employ a compound pulley and head-gear such as I have used for a long time while adjusting the plaster-of-Paris jacket in the treatment of Pott's disease. I believe that the superincumbent weight can be much more effectually removed from the bodies of the vertebrae, hence the spinal column much more completely straightened, by causing the patient to raise himself by lifting from the occiput and chin than by any other method that has been adopted. I therefore attach the pulley, cross-bar, and head-piece to a hook over the patient's head (a tripod with long legs and a hook above is commonly employed), adjust the head-piece so as to draw equally upon the occiput and chin, and then cause him to raise himself by drawing slowly and steadily upon the cord passing over the pulley above. (See Fig. 1.)

FIG. 1.

I believe that no harm will come from this method of suspension providing the hands of the patient are not permitted to come below a level with the forehead. They should be held high over the head, thus calling into action the muscles of the thorax, and obviating undue traction upon the neck.

(Three adults then suspended themselves with perfect ease.)

While suspended the patients should be required to take three full inspirations. A marked change will

then take place in the appearance of the back; the curves will become more or less completely obliterated. (See Figs. 2 and 3.)

In treatment the patients should be required to practise self-suspension two or three times a day, maintaining the position for two or three minutes each time.

#### PRECAUTION.

The self-suspending apparatus should never be used by the patient unless under the immediate supervision of some attendant, for the following reason: The pulley is a compound one, and if the cords become twisted upon themselves in any way, it may be easily rendered immovable. Now if the child should be permitted to put on the head-piece and draw himself up, and then, as he might do in his childish fancy, take a notion to swing around, or should accidentally do so he would probably become permanently sus-

FIG. 2.

ended, and the result might be disastrous. For that reason the tripods have been made by Mr. John Reynlders, instrument-maker of this city, varying in height according to the requirements of each patient, which can be readily set up at any time and placed where the mother or some other attendant can superintend the exercise. They have also been made with joints, so that they can be folded and readily packed in a trunk, and in that manner the whole apparatus has been made portable.

After six or eight days, more or less, and while suspended, a plaster-of-Paris jacket is applied in the same manner as for Pott's disease. The suspension, however, while the jacket is being applied, as a rule, should be made from the axilla as well as from the occiput and chin, for the reason that the patient can not suspend himself sufficiently long to allow of its proper adjustment. I believe that it would be better, were it possible, to adjust the jacket while the

patient keeps up self-suspension from the head as described.

[An intelligent gentleman (a member of the medical profession), who was present for the purpose of having a jacket applied, believed that he could maintain the self-suspended position a sufficient length of time, and accordingly the experiment was made for the first time, and with complete success. See Fig. 3.]

FIG. 3.

In general, however, I believe it to be safer to suspend the patient from the axilla, occiput, and chin rather than from the occiput and chin alone, while the jacket is being adjusted. (See Fig. 4.)

#### ACCESSORY APPARATUS WHEN THE AFFECTION INVOLVES THE CERVICAL VERTEBRÆ.

In cases in which it becomes desirable to employ some measure to rectify the deformity in the cervical region, what had been called "The outside Jury-mast," is recommended. It consists of a plate composed of cast and malleable iron, with an upright rod curving over the top of the head, and terminating in a hook for the attachment of the head-piece to be buckled under the chin and occiput. To the lower and malleable portion, which is to be bent to suit the surface to which it is applied, are attached strips of perforated tin as seen in the illustration. (See Fig. 5.)

While adjusting the jacket, the "jury-mast" is o

be secured in its proper position by the successive layers of bandage, and when the plaster becomes set, a firm support is given from which traction can be made upon the occiput and chin by means of the leathern head-piece.

SUBSEQUENT TREATMENT.

The patient should be required to practice self-suspension after, the same as before, the application of the jacket; and as soon as the straightening of the spine becomes sufficient to render the jacket loose, it should be removed and another applied. Such treatment should be continued until the deformity has been nearly or entirely overcome, when a corset such as I have recently had made by Mrs. Drury, of this city, may be worn with advantage.

SUCCESS OF THE TREATMENT.

This plan of treatment has in my hands been far more successful than any which I have ever employed; and the patients have worn the jacket with far less discomfort than any device in the way of instruments that I have ever seen. I believe the plaster-of-Paris jacket to be better adapted to the treatment of rotary-lateral curvature of the spine than any instrument

FIG. 4.

which has ever been devised, and in my opinion has the following advantages:

*First.* It affords a means of treatment which is within the reach of every intelligent practitioner.

*Second.* It affords the best means for keeping the superincumbent weight from the bodies of the vertebrae after such weight has been removed by suspending the patient either from the axilla, occiput, and chin, or from the occiput and chin aided by the thoracic muscles acting through the arms.

*Third.* It could be worn without discomfort if properly adjusted.

I have formerly recommended this class of patients to wear Banning's brace, which I have regarded as the most perfect instrument that has been devised; but the results obtained with the plaster-of-Paris jacket have been far more satisfactory both to myself and to my patients.

One of the most striking effects produced by wearing the jacket has been a change for the better in the countenance of the patient; and that change I have been disposed to attribute to the increased supply of oxygen afforded by virtue of an increased breathing capacity.

LUNG CAPACITY AS MEASURED BY THE SPIROMETER.

To determine whether a greater amount of air can be introduced into the lungs after than before the application of the plaster-of-Paris jacket, the men are required to use the spirometer, when it is found that the capacity of the lungs for receiving air is notably increased. [Dr. Sass' and Mr. Reynders' instruments

FIG. 5.

were employed, and the capacity of one patient was increased from 140 (expiration) and 100 (inspiration) to 180 and 130; and upon second trial, after the application of the jacket, the capacity reached 200 (expiration) and 140 (inspiration).]

CHANGE IN HEIGHT.

[In one patient upon whom the apparatus was applied during the lecture, the difference in height before and after suspension was 2 3/4 inches. The same man gave as reasons for wearing the jacket, although his case was incurable, that it gave him support, was easily worn, increased his general strength and health, and afforded more vital heat.]

A YOUNG MOTHER.—An esteemed and entirely trustworthy correspondent has furnished us with the following facts touching a case which came under his observation. As an instance of early maternity, the case is one which certainly vies with any case on record. The girl first menstruated when ten years and six months of age. She became pregnant at eleven years and six months, and was safely delivered of a male child January 19, 1875. The reputed father of the child was, at the time, a hopeful of fourteen years of age. The child is still alive, but not very strong or bright, although the promising parents are doing as well as could be expected.—*Detroit Medical Journal.*

## Original Communications.

### CASE OF VESICO-ABDOMINAL FISTULA OF FOURTEEN YEARS' STANDING.—CURE.

By JOSEPH WORSTER, M.D.

NEW YORK.

DESCRIPTION OF THE CASE.—Miss H—, twenty-one years of age, daughter of a captain in the commercial marine, of good constitution and in good health until she was eight years of age, when she was prostrated with a severe attack of diphtheria, from which she apparently recovered under the usual treatment, but which left certain *vestigia*. Among them were incontinence of urine and catarrh of the bladder as the direct exponents of the diphtherial taint. The mental symptoms were, however, the more noticeable of the two classes. Besides extreme and habitual depression of spirits, according to the description of her mother, she suffered a very complete transformation in her habits; lost all disposition to engage in the amusements common to children of her age, and all relish for them, and appeared to regard the games practised by her playmates with decided aversion. Habitual insomnia supervened; such that she lay awake night after night, but at daylight would often drop into a doze of short duration. Whether this was primarily due to her dread of the dark, which was accompanied with an impression that she should die if she was left alone in it, or to the purely physiological causes of which that dread was the psychical exponent, there are no data for determining with certainty.

About this date her ability to stand erect became impaired, for causes that will appear hereafter, and she contracted a habit of standing with a forward bend of the body, the angle of inclination being about forty-five degrees—a phenomenon evidently resulting from peritoneal adhesions. She also became incapable of stooping to pick up anything.

Two years after the date of the attack of diphtheria, cystitis, accompanied with a copious flux of purulent matter from the urethra, supervened. This was immediately succeeded by a tumefaction in the umbilical region, which was followed in due season by large and repeated purulent discharges from the umbilical opening, and subsequently by discharges of urine. The inflammation in that quarter now gradually subsided, although, with occasional purulency, the urinal discharges continued by way of the umbilical opening, to the exclusion and complete subversion of the natural function of the urethra. These discharges appeared to find their way from the bladder to the umbilical opening by means of the urachus, thus presenting a practical return to the process of excretion that obtains during fetal development. This view of the case was subsequently confirmed; for, during her eleventh year, and in the third year after the attack, after a severe contusion on the linea alba, a new tumefaction presented itself a little lower down, between the navel and the pubes, at about one-third the distance from the latter. It was at first very purple and inflamed, but gradually subsided on the appearance of a transparent spot. This entire tumefaction, which was about two inches in diameter, disappeared altogether as the spot became more and more transparent, and the latter suddenly opened and afforded exit to a considerable accumulation of urine,

which obviously proceeded from the vesicular extremity of the urachus. On questioning the parents closely, there appears to have been no sufficient cause for this in any detention of the urine by way of the urethra with consequent pressure. Judging from her mother's statements, the sloughing at this point was very considerable and prolonged; and for two years the opening was of sufficient dimensions to admit of exploring the bladder with the fingers. It should, however, have been premised that the patient had an attack of scarlet fever but a short time previous to the occurrence of the second opening, although there is no evidence that this feature of the case was in any degree determined by that event, and the local contusion appears to have been mainly responsible for this later aspect.

At sixteen years of age the catamenia supervened very naturally and without unusual disturbance, and the patient's general health improved so materially that her parents were so far encouraged as to anticipate that, with proper surgical treatment, a complete recovery might be effected. From that date until she was twenty-one years of age, the patient was under constant medical treatment, and had been examined by several eminent European physicians, who declined to operate, although her general health was such as could only be described by the term robust, when her case was first brought to my notice by her father.

Before entering upon the operation, I shall be pardoned, perhaps, if I enter upon a brief discussion of purely physiological and anatomical interest, in explanation of the reversion to the fetal manner of excretion presented by the case, particularly as it is a somewhat extraordinary feature. Anatomists are well aware that the urachus is simply a tube leading from the fetal bladder to a membranous sac designated as the allantois, situated external to the embryo *in utero*, and receiving the fetal urine. At this period the round ligaments of the bladder are represented by the umbilical arteries which convey the effete fetal blood to the placenta, where it is regenerated, but which, with the exception of their pelvic extremities that become the trunks of the internal iliaes, are afterwards converted into ligamentous cords, by the deposition of tissue partly, and partly by contraction. The duct familiar to anatomists as the urachus is situated between these two arteries, and after the establishment of the adult manner of excretion, by way of the urethra, is gradually obliterated so completely that its course is not distinctly traceable in dissecting the mature organism. The several stages of this obliteration have not been made out in detail, from actual observation, so thoroughly as could be wished; but it has not hitherto been supposed that sufficient vestiges were left even at eight years of age to admit of a reversion to the original type of excretion, under any morbid conditions arising from the histolytic tendency associated with the introduction of poison into the system. In this case the adult manner of excreting urine had been thoroughly established for eight years previous to the introduction of the diphtherial poison; and yet its histolytic action was sufficient to break down a tissue of not very recent formation and open a passage that had been obliterated for years, and of which, for the most part of its length, all visible traces had disappeared. The structural changes that followed in such rapid succession in this region, and the general nervous disturbance which was their exponent, were exactly such as would naturally be anticipated, as the successive steps of the reversion that finally supervened and maintained itself for years. The reversion being established, the cata-

menia came on normally, and there was a very material improvement of the general health; that is to say, the system readily adjusted itself to the morbid process represented by the fistula, and the urethral passage might in its turn have ultimately become obliterated, without materially impairing the general health of the patient. The time of obliteration varies somewhat, and occasionally at birth the urachus is still open, and the urine is discharged in that manner. In the case of Miss H—, aside from the long-continued perviousness of this canal, it had, together with the hypogastric arteries, formed a hardened and fibrous cord about two inches in diameter, very uniform throughout its whole length, and capable of compression between the thumb and finger, which extended from the bladder to the umbilical opening, throughout the entire length of the linea alba. This cord appeared to consist of peritoneal adhesions, in the mass of which the fistula was formed. Primarily, of course, its issue was at the umbilical opening; but subsequently, when the peritoneal adhesions which had prevented her from standing erect gave way, and the tendency to forward inclination of the body was corrected, the fistula broke out and terminated in the upper portion of the anterior space, not connected with the peritoneum. Its later form was consequently a slight modification of the foetal process, and, according to comparative anatomists with whom I have discussed it, presented, as respects the cord-like mass and the involution of the hypogastric arteries, a striking anatomical analogy with the male urinary process in the rodents. A thorough study of the data that comparative embryology furnishes will enable the reader to form a definite idea of the relation to each other of the successive transformations in the case, but will not especially profit the practical surgeon.

*Operation, April 14, 1875.*—Being satisfied from examination that the sphincter of the bladder was capable of retaining the urine after closing the fistula, if an operation for that purpose should be successful—an opinion in which, after an examination with me, Dr. J. Marion Sims concurred—I determined on operating, and accordingly syringed out the bladder with about a pint of carbolic acid water, 5i. to Oij., using Nott's return current instrument, and leaving in Sims' sigmoid catheter. With the valuable assistance of Dr. Charles Leale, Dr. Willard Parker Werster, and Dr. G. M. Crosby, the patient was placed under the influence of an anæsthetic, and the operation was commenced by making two elliptical incisions, the ends of which met above and below the old cicatrix, thus excising most of it with the existing fistula. These elliptical cuts were directed obliquely from above, downward and inward, in the direction of a centre, so as to make them meet near and above or external to the peritoneum. I unintentionally cut through the latter about three quarters of an inch in the upper angle of the incisions, thus giving my assistants some trouble in keeping back the omentum, which, of course, protruded at the opening thus made, while I was passing the sutures. In closing the wound, the needles were passed about half an inch back from the edge of the incised integument, and carried down near the peritoneum, but not so deep as to interfere with it or in any way to wound it. Seven silver sutures were passed, closing the opening with an easy and well-distributed tension. The entire operation, inclusive of dressing, occupied, according to Dr. Leale's memoranda, only ten minutes. The adjustment of a bandage and the injection of five minims of morphia with the hypodermic syringe completed the work. At ten o'clock in the evening, water was

draining off freely by way of the urethra with Sims' sigmoid catheter, and was caught in a vessel adjusted for the purpose. The pulse was 80. There was no special tenderness in the region of the linea alba. The patient was somewhat thirsty, but not more so than would naturally occur after the administration of an anæsthetic. No moisture exuded from the track of the old fistula.

*April 15.*—Comfortable; had no pain during the night. About two quarts of water had drained off through the sigmoid catheter. The sutures had taken well and without inflammation. No moisture appeared to come from the track of the fistula, but water continued to pass freely through the catheter.

*April 16.*—A slight leakage was detected in the region of the excision, escaping through the location of a ligature which had been applied to a small artery, which gave exit to a small quantity of fluid that, after careful examination, seemed to be serum. Pulse 78; no tenderness of the peritoneum. The usual nausea, consequent upon the administration of anæsthetics, had been somewhat troublesome, but had nearly subsided. Ordered a teaspoonful of iced brandy to be given as occasion should require, which seemed to have the desired effect.

*April 17.*—The leakage had somewhat increased, and appeared to be freest while the drain from the urethra was most abundant. It was, however, without any odor of urine, and came no doubt from the accidental peritoneal opening. A careful examination indicated serum.

*April 18.*—The escape of fluid from the incision had completely ceased during the preceding twenty-four hours. The pulse was 78 and the skin moist; no peritoneal tenderness; tongue slightly furred and yellow. Patient was comfortable and able to take food in sufficient quantity.

*April 22.*—(Eight days after the operation.) On removing the dressings I found one of the sutures cut through in consequence of flatus in the abdomen, and the escape of urine as free as ever. I resolved to operate immediately, and did so by cutting out the track of the needles and removing the remainder of the old cicatrix; want of solidity in the more recently formed tissue having, as I believed, been the cause of the sutures giving way. I did not, therefore, consider it safe to rely for cicatrization on anything except the sound and fully developed integument of the abdomen. Accordingly, with the same assistants as before, with the exception of Dr. Leale who had gone to the country, the patient was again placed under anæsthesia; and with two 3¼-inch incisions, the sutures having been previously removed, I excised all traces of the former operation, making the walls of the new operation very oblique; introduced the needles six lines back from the tegumentary edge, and returned the sutures, so graduated as to distance, as not to be more than two lines apart. Used the ordinary silver suture and gave a firmer twist than in the previous operation; the greater solidity of the integuments admitting of a higher degree of tension. Then applied short and narrow straps between the sutures, with a strip of lint over the twists, and a succession of long straps over the lint. Finally, at the suggestion of Dr. Willard Parker Werster, I applied a girdle of adhesive plaster, six inches in width, around the body, after the manner of a bandage, the ends being split into many strips to admit of an intertexture at the meeting edges. Each strip was secured with a pin, so that there should be no retraction of the general edge by the slipping of the plaster. The sutures were thus prevented from being loosened or

torn out in case of flatus or vomiting. This dressing was not disturbed for twelve days. On removing it in the course of the thirteenth day the adhesion was perfect. I accordingly removed the sutures and redressed the wound, which required some attention to facilitate the renewal of the excised integumental tissue and the healing of the needle punctures. Renewed the dressing after cleansing the wound with carbolic acid water, readjusted the zone of adhesive plaster, and resorted to the additional security of a common bandage over the whole. After this the dressings were renewed on every alternate day. At three different times, intervals of several days intervening, I found a slight leakage from the deep punctures made by the needles, which, on microscopic examination by Dr. T. E. Satterthwaite, proved to be nothing but serum exuding from the accidental incision of the peritoneum. These wounds, however, gradually cicatrized and, in six weeks from the date of the first operation, the patient was convalescing rapidly. The sigmoid catheter was retained in the urethra until the wound was completely healed externally. On its removal the patient retained the urine for two hours without inconvenience, and was soon able to take rambles about the city without troublesome inclination to urinate.

One very extraordinary feature connected with the case, and one of considerable interest to thoughtful physiologists, consists in the long-continued perviousness of the urachus—the remains of an obliterated canal existing in the fetal stage, and connecting the cavity of the bladder with a membranous sac known as the allantois, which is externally placed and receives the fetal urine. At birth this canal is occasionally unobliterated, and the urine escapes by way of the umbilical opening. The whole cord, together with the hypogastric arteries, formed a hardened, fibrous, and cord-like mass of about two inches in diameter, capable of compression between the thumb and finger, and of uniform size throughout the whole length of the linea alba from the bladder to the umbilicus. The upper part, from the bladder to the umbilicus, appeared to consist of peritoneal adhesions, and in this mass the fistula was found. Its issue was primarily at the umbilical opening. Subsequently, however, the peritoneal adhesions, which had eventuated in the forward inclination of body, gave way, the body became again erect, and the fistula broke out and terminated in the upper portion of the anterior space, not connected with the peritoneum; the whole constituting at first a fistulous reversion to the fetal process, which was finally somewhat modified, but continued substantially to repeat and continue that process until the patient was twenty-one years of age. The reader who is curious to pursue the literature of this subject will find much important information in the *Dictionnaire des Sciences Médicales*, volume xxxviii., article *Ouraque*, in Todd's *Cyclopædia of Anatomy and Physiology*, volume i., page 393, and in a paper by Dr. J. J. Charles, read before the surgical section of the British Medical Association in 1875, and published in the 1875 volume of the *British Medical Journal*.

**NITRIC ACID FOR HOARSENESS.**—Dr. W. Handsell Griffiths says that a few drops of nitric acid in a glass of sweetened water, a couple of times daily, will be found an excellent remedy for the hoarseness of singers. One of the largest fees ever received by him—so he says—was for this prescription.—*Southern Medical Record*.

## SOME USES OF VASOLINE AND SALICYLIC ACID IN OBSTETRICS.

By HENRY A. DUBOIS, M.D.,

SAN RAFAEL, CAL.

In a recent number of the *MEDICAL RECORD* I called attention to the use of vasoline and salicylic acid in the healing of wounds; in the present I propose briefly to mention some of the various uses for which this compound seems to be adapted. Vasoline, or cosmoline, as it is frequently called, is a hydrocarbon made from petroleum by simple evaporation and clarification. It is very cheap, being worth only some forty to fifty cents a pound. It has no taste or smell. Its rôle as a protective against the action of the air is extensive, as in burns, excoriations, etc. It is one of the best of lubricants. Its use in simple and especially in complicated labors is thus very advantageous. Internally, it seems to relieve irritation of the mucous membrane, and, when taken up by the system, though it undergoes no proper digestion, to act much in the same way as cod-liver oil. As a vehicle for more active agents, it is more generally useful than any other oil-like compound. Salicylic acid has of late come into vogue, and is now used for a great variety of purposes—principally as an antiseptic, to reduce the heat of the body, and in diseases in which there is a morbid material in the blood, as in rheumatism and gout, etc. It is not expensive, costing from thirty to forty cents an ounce. I have tried several samples of different manufacture, and find that of Rosengarten, of Philadelphia, by far the best, while the German article that I have used has proved caustic and utterly unfit for many purposes. The American acid is in silky, white crystals, like quinine, has no caustic taste, and, mixed with vasoline, makes a homogeneous ointment. The German is amorphous, looks like chalk, has a slight pinkish color and caustic taste, and, mixed with vasoline, makes a lumpy, irritating ointment, unfit for use.

With these few preliminary remarks, I will now briefly notice some of the many uses of these two valuable agents; and first as to their use in obstetrics. It has been my practice for some time back to use vasoline, with a grain or more of salicylic acid to the ounce, and scented with a drop of otto of roses, in all vaginal examinations, instead of oil or soap. I believe I thereby more certainly avoid carrying infection from case to case than I should otherwise do. In first confinements it may be used in the first state of the labor, so soon as the woman takes to bed. I make use of a glass syringe, an inch in diameter and without a nozzle. With an instrument of this kind an ounce or more of the semi-solid vasoline can be introduced up to the os, where it remains at the temperature of the body, in a semi-solid state. I use it in this way as a simple lubricant, and without the addition of the acid. If desirable, in certain cases, it can be combined with the extract of belladonna, and, after the labor is completed, with the extract of ergot, or, in case of hemorrhage, with the liq. ferri persulphatis, with all of which it mixes well. If it is desired to introduce it into the uterus, it can be rendered fluid by putting the bottle containing it into water of a temperature of 110° F., when it can be used with the ordinary uterine syringe. In the course of a labor I use three to six ounces, with the effect, as I claim, of shortening the first stage of labor and rendering the parts, especially in first labors, easily dilatable in the second stage while, after the placenta is delivered, a small quantity of the vasoline, with the acid added, disinfects the

discharges, and does much, it seems to me, to prevent purulent absorption. Indeed, if puerperal fever was prevalent, I should not hesitate to introduce it freely into the uterus immediately after confinement. To illustrate the healing qualities of this combination, I some time ago had an extensive rupture of the perineum in a primipara, due to an unusually large child and to an unyielding perineum. I passed two pins through the lips of the wound and a figure-of-eight around each, and directed the patient to introduce a little of the vasoline ointment two or three times a day on her finger. On the third day after, when I next saw her, on removing the pins I found the wound entirely healed. My cases are not sufficient to base positive conclusions on, but I am inclined to think that an hour or more can be saved in an ordinary labor by the use of the vasoline, and that the second stage will go on easier, owing to a more thorough relaxation of the soft parts, and to the avoidance of unnecessary friction, and that its use with the acid after labor will do much to prevent puerperal absorption, and, in any event, will conduce to the comfort of the patient. In dilating the os with the sponge tent, I find that by coating it with the vasoline and the acid (ten grs. to the ounce), I can more readily introduce it, the tent not expanding at first, owing to the coating of vasoline; but, if held for a moment or two in place, it will remain without danger of its coming away, and will expand to the same limits that it would have done without the coating of vasoline, as can easily be proved by putting two tents in water, one coated and the other not. In erosions of the os, after the engorgement of the parts is removed by glycerine pads, the vasoline and acid ointment, applied on cotton-wool, will do much to effect a speedy cure, especially if alternated with the glycerine. There is one use for this ointment that I have not fully worked out. Physicians are frequently applied to to produce abortion. Recently, on the same day, two women came to me; the reason assigned in the one case was that the husband was syphilitic; in the other, that pregnancy brought on violent attacks of spasmodic asthma. Of course I explained that the child had rights as well as the mother, but it was all that I could do to prevent one of these cases from going to a professed abortionist. In some cases of this kind prevention is better than cure, and I am inclined to think, from some experiments, that vasoline, charged with four to five grains of salicylic acid, will destroy spermatozoa, without injury to the uterus or vagina.

In conclusion, there are a number of uses for vasoline in the lying-in-room and nursery. I make no claim to its being "a cure-all," but it is a great convenience, and its "rôle" is extensive. The ointment makes a good dressing for the umbilical cord. Vasoline answers better than oil or soap to remove the cerumen from the newly-born infant. Mixed with an equal weight of honey and ten grs. of borax or of chlorate of potassa to the ounce, it answers an excellent purpose in cases of thrush. The ointment alone, or mixed with ten grs. of quinine to the ounce, quickly removes the small worms that frequently infect the anus of young children. In the excoriations of infants it effects rapid healing. In the not uncommon sore eyes of the first few days of life the vasoline alone, introduced within the eyelids, effects a cure in a day or two. Again, in the "snuffles" of the old women, which, by preventing nursing, frequently seriously affects the health of the infant, it, when introduced into the nostrils with a camel's-hair pencil, answers better than anything I have as yet tried, especially if the head is kept warm with a flannel cap

There are many other uses for vasoline, alone or combined with varying proportions of salicylic acid, that the experience of the physician will readily suggest to him in this connection. There yet remains to be considered some of the uses of these agents in other departments of medicine, which, in a future number of this journal, I will briefly refer to.

## Reports of Hospitals.

### BELLEVUE HOSPITAL.

#### NOTES OF PRACTICE AND PECULIARITIES OF TREATMENT.

##### CHRONIC BRIGHT'S DISEASE—A PECULIAR, AND ALMOST UNMISTAKABLE, SYMPTOM.

As the visiting physician was walking across one of the wards, his attention was directed to a male patient upon the opposite side, and he remarked: "That man has Bright's disease." There was present none of that peculiar pale color of the face, so long recognized as belonging to the facies of Bright's disease, but there was an "unmeaning stare" in the patient's eyes, that gave rise to the snap diagnosis. The subsequent examination of the patient revealed the presence of moderate œdema of the feet and ankles, persistent headache, occasional attacks of nausea, steady loss of flesh and strength, urine with a specific gravity of 1010, and containing albumen to one-third its bulk. No examination had been made for casts. It was the "unmeaning stare," the dulness and sluggishness of the pupil, well-dilated, which was regarded as almost unmistakable evidence of chronic Bright's disease. There were some forms of hysteria in which such characteristic expression might be seen, but when present in male patients it was very much more likely to be evidence of kidney disease; it should suggest a thorough examination of the urine and analysis of the case. The following

#### TREATMENT

was recommended. Make the diet as little nitrogenous as possible. Use milk freely. Iron and cod-liver oil were recommended for the purpose of making up the deficiency produced in the red corpuscles by the increase in the elimination of albumen. To assist the iron, it was combined with nux vomica and sweet spirits of nitre, according to the following formula:

R. Tr. ferri muriat. .... gttss. x.  
Tr. nucis vom. .... gttss. x.  
Spts. ætheris nitras ..... ʒi.

M.

To be taken three times a day.

If gastritis troubled the patient, the iron and cod-liver oil were to be stopped, and a saline purge to be administered—cream of tartar being regarded as the best. Large doses of pepsin and oxalate of cerium might be used to quiet the stomach. The specific treatment for the disease consisted in the use of the following:

R. Hydrarg. bichlorid ..... gr. ʒi.  
Digitalis ..... gr. i.  
Quin. sulph ..... gr. i.

M.

To be given three times a day.

The skin was to be freely rubbed with olive oil twice a day.

**ARGYRIA—A METHOD OF ADMINISTERING NITRATE OF SILVER WITHOUT PRODUCING DISCOLORATION OF THE SKIN.**

The patient, a young man about twenty years of age, had taken sufficient of nitrate of silver to produce marked discoloration of the skin. It was said by the clinical teacher that nitrate of silver could be used for two or three years without producing such effect, if given in half-grain doses three times a day, until sixty, perhaps eighty, grains had been given, and then making an interval of two or three weeks. At the close of the vacation the remedy could be resumed, and when the stated number of grains had been taken, another interval was to be made, and so on.

**LOCOMOTOR ATAXIA—ABSENCE OF DISORDER OF THE OPTIC APPARATUS.**

The case before us was exceptional, from the fact that the patient had had no disturbance whatever of the optic apparatus, and yet the symptoms of locomotor ataxia were so well marked as to leave no doubt regarding the diagnosis. It was the fourth case in which disturbance of vision had been absent, and yet the other symptoms of the disease had been well developed. These cases were interesting, because disturbances of the optic apparatus is an early and very frequent symptom of locomotor ataxia.

## Progress of Medical Science.

**DEGENERATION OF NERVE FIBRES.**—The excellent investigations of Ranvier have opened for us an entirely new view of the structure and life of the nerve fibre. His recent investigations appear to show that the medullated nerve fibre is not a simple organic or physiological unit, but is rather a combination of units, and is to be regarded as a chain of single nucleated cells. Each fibre shows at regular distances annular constrictions of the sheath of Schwann, with corresponding interruptions of the medullary sheath (Frey's *Compend. of Histology*, Amer. Ed., p. 195, Fig. 171). The distance between the constrictions is pretty uniform for each fibre, and increases in proportion to the thickness of the latter. The interval between each two is usually from one to two millimetres. Midway between each two constrictions, at the inner surface of the sheath of Schwann, and in a trough-shaped excavation of the medullary sheath, lies a cell nucleus, surrounded by protoplasm. Under the action of a dilute solution of nitrate of silver, the boundaries between the fibre segments become brown. This occurs later in the constrictions of the sheath of Schwann, and still later in the axis-cylinder at the level of the constrictions. It would appear, therefore, that each fibre segment has the morphological value of a cell unit.

Hitherto the opinion has generally prevailed that the axis-cylinder formed a continuous, entirely unbroken cord, throughout the entire length of a fibre, there being in every part of it the same conditions for the transmission of the excitation. Engelmann appears to have shown experimentally that such is not the case, and that a discontinuity of the axis-cylinder exists at the cell boundaries, each cell having its own axis-cylinder, which during life is in intimate contact, but not in actual continuity, with that of the two adjacent cells. The excitation is transmitted by contact from cell to cell; but, in the process of death, each cell dies independently of its neighbor, the pro-

cess never being communicated by contact; the cell boundary is rather an impediment to such a communication.

The observations on which these conclusions are based were made, for the most part, on the sciatic nerves of frogs. The nerve trunk was carefully isolated for a short distance, and a piece, 2 to 4 mm. long, removed with very sharp, pointed scissors. Osmic acid, carmine, and picro-carmin were used to render the nerve changes evident. Engelmann found that in the divided nerve the process of degeneration was propagated from the point of injury—in the central portion in a centripetal, in the peripheral in a centrifugal direction—within each nerve fibre, as far as the next Ranvier's constriction. *The latter was never overstepped.* In the central stump the degenerative occurrences were limited to this purely local process—that is, only the directly injured cells died. In the peripheral stump, however, there was added to the latter a process of degeneration which apparently commenced simultaneously throughout the entire length of the nerve trunk, and was not caused by the mechanical injury as such, but depended on the discontinuity of the connection with the centrum thus produced. Accurate examination, with higher magnifying powers, of the central stump, after a careful separation of the fibres, presented the unequivocal fact that within the majority of the fibres the degenerative process extended accurately to the next Ranvier's constriction, beyond which the fibre suddenly assumed its normal appearance. In many fibres, where the next Ranvier's constrictions were far from the cut surface, the degenerative process did not extend to the next cell boundary. In these the degenerated part gradually passed over into the normal part. Months after the division of the nerve, when the process of degeneration had reached its highest degree, the cell beyond the first Ranvier's constriction, in the central stump, was always found to be normal. During the process of degeneration the nuclei of the nerve fibres and the protoplasm surrounding the former do not undergo any change worthy of mention. The former do not present any sign of proliferation or division.

The discontinuity above demonstrated is also shown by the fact that in picking nerve fibres apart, after they have been treated with nitrate of silver, the axis-cylinder frequently breaks exactly at the Ranvier's constriction, while the tearing of the sheath of Schwann and of the medullary sheath has occurred at another place. The axis-cylinder is then seen to project naked for a long distance beyond the sheaths, and the characteristic brown tinge of the free end of the cylinder shows that the separation has occurred exactly at the level of a Ranvier's constriction. At the same time the regular and square form of this free end shows that it pre-existed as such within the fibre.—*Onderzoekingen gedaan in het Phys. Lab. der Utrechtsche Hoog-school, Derde Reeks, IV. A. 1.*

**A CASE OF SPASMODIC INFANTILE CEREBRAL HEMIPLEGIA.**—Experiments on animals have demonstrated that the psycho-motor centres for the limbs are located in the frontal and ascending parietal convolutions and in the paracentral lobe. The microscope has shown that the nerve cells in these regions are larger than in other parts of the brain, and they have been called giant, or motor cells. Pathological anatomy and clinical observation, in their turn, have taught us that lesions of these same convolutions in man produce a special train of symptoms. The following case, which was observed in the wards of M. Charcot, at la Salpê-

trière, is an example of a lesion partly confined to these convulsions:

Marie L—, aged 18, entered the hospital on June 21, 1875. Father died of apoplexy. At the age of five and a half years the patient was well developed, intelligent, and able to read and write. At this time it was noticed that she suffered from a sort of vertigo whenever she went into a large street, but that she never had the attacks when in narrow streets, however crowded. When about six years old, during convalescence from measles, she was seized with convulsions that lasted seven hours, and left behind a certain degree of weakness in the left side. Two months later a new attack of convulsions occurred; they began in the left foot, and were accompanied by severe pains. The convulsions spread gradually, involving the left leg and arm, and the left side of the head, and the patient then became unconscious. From the sixth to the eighth year she suffered from pains and shocks in the left arm. From the eighth to the eleventh year she had attacks resembling *petit mal*. During this period she became exceedingly irascible, and the left foot became slightly deformed. When she was eleven and a half years old her menses appeared; the fits of anger now ceased, but were replaced by various eccentricities. From that time the convulsive attacks became more and more frequent and severe; the intelligence decreased; the paralysis of the left side became marked, and finally locomotion became impossible. The attacks were preceded by prodromata and an aura, and constituted veritable epileptic fits, which were complicated by delirium. These fits, however, differed in some respects from ordinary epileptic attacks; for instance, the temperature scarcely passed 102° F., in spite of the repetition of the fits. When admitted to the hospital, the patient spoke and acted like a child of eight or ten years. The left arm and leg were somewhat rigid, and were less developed than the right. The left foot was in the position of marked equino-varus. The fits, after a while, became very frequent, and the patient finally became permanently unconscious. Pneumonia set in, and she died, comatose, on December 2d.

*Autopsy.*—*Brain:* Right hemisphere smaller than the left. A morbid centre of long standing occupied: 1, the posterior third of the median and superior frontal convolution; 2, the upper part of the ascending frontal convolution; 3, the paracentral lobule; finally, the ascending parietal convolution was considerably atrophied in its upper third, and tapered off as it approached the morbid centre. The lesion consisted in a cellular infiltration, both of the gray substance of the convolutions in the parts indicated above, and of the white substance as far as the wall of the ventricle. The affected convolutions, although much atrophied, still retained to some extent their original forms, and did not present a yellow coloration. A section through their cortical substance revealed a large number of pyramidal cells, with strongly refracting margins; the cells still retained their processes, and were filled with very dark granules, apparently constituting a sort of calcareous infiltration or degeneration. A transverse section through the affected part showed that the lateral ventricle was dilated; that the lesion extended to the ventricular wall; that the *capsula interna* on the right side was notably atrophied; and that the *nucleus caudatus* and *nucleus lentiformis* were smaller than on the left side. The thalamus opticus and corpus striatum were not altered. *Left hemisphere* normal. The *corpus mamillarium*, the *cerebral peduncle*, and the *anterior pyramid* on the right side were atrophied, but natural in color. A section through the cord above the decussation revealed manifest atrophy without gray dis-

coloration of the antero-lateral column on the left side, and a displacement of the anterior median fissure towards the left side. There was, therefore, well-marked *secondary degeneration*. The inferior lobe of the left lung showed red hepatization. The other organs were normal.—*Gazette Médicale de Paris*, 9th and 16th Dec.

ON THE IMMEDIATE CURE OF PILES.—Mr. Reeves, of Edinburgh, has adopted a plan of treating internal piles to which he has given the term "immediate cure." The operation is rapid and the entire treatment short as compared with the ordinary method, viz., by nitric acid, ligature, clamp, and cautery. He thinks, moreover, that it is free from danger and does not always require an anæsthetic. The piles being well down are punctured to their bases by the conical tip of the gas cautery (Dr. Paquelin's). The number of the punctures varies with the number and size of the piles, a pile the size of a half walnut requiring two or three. A dull red heat should be employed, and the point of the instrument is to be gently rotated while it is within, otherwise a portion of the eschar will be withdrawn, and then hemorrhage may ensue. Ulcers or fissures should be cauterized at the same time. Should there be any oozing a touch of the cautery will stop it. The piles are then to be returned and a half-grain morphia suppository inserted. After the bowels have been confined for four or five days a warm injection is to be given, and followed upon the succeeding day by a laxative. At the expiration of a week the patients are discharged. Of eighteen cases thus operated on two were not allowed out for ten days and one for a fortnight, but in these cases there was some uterine or urinary complication. All the patients were examined subsequently, and it was exceedingly difficult to discover by the finger or the speculum that there were any cicatrices following the operation.—*Lancet*, February 17, 1877.

THE GERMS OF BACTERIA IN SUSPENSION IN WATER.—MM. Pasteur and Joubert have been engaged of late in the study of the germs of inferior organisms which are contained in water, and at a recent meeting of the *Académie des Sciences* presented the following as the first conclusions at which they had arrived:

1. The germs of bacteria are so numerous in certain waters, for instance in that of the Seine, that a drop of this water, taken either above or below Paris, is always fruitful, and from it many kinds of bacteria may be developed. Some of these germs resist a temperature of over 212 degrees F., while in a moist state, provided the menstruum is not acid; and in dry air resist a temperature of 266 degrees F. for several minutes. These last germs are identical with those studied by Pasteur in 1862, which were derived from the atmospheric dust and resisted a temperature of 212 degrees F.

2. The ordinary distilled water of the laboratories always contained germs, though in less numbers than ordinary water.

3. Water distilled in vessels from which absolutely all foreign germs have been removed is perfectly pure, that is, it is exempt from the germs of inferior organisms.

4. In water taken from springs as they gush from the interior of the earth, before it has been contaminated by dust from the atmosphere, or from the surface of the ground, or by surface water, no traces of the germs of bacteria can be discovered.

5. The germs in question are so small that they pass through all filters, and although so numerous in water that a single drop of it will invariably contain them, they usually do not make it turbid; it may be as perfectly transparent as distilled water.—*Gazette Médicale de Paris*, February 10, 1877.

# THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, March 31, 1877.

## CHEAP MEDICAL EDUCATION.

A LETTER in another column, taking exception to some remarks made by us on cheap medical education, invites a discussion of the subject in some of its more general aspects. We readily admit that there are two sides to the question, and that a cheap college may give a good and thorough course of instruction. We believe, however, on general principles, that it is oftener the exception than the rule. It can hardly be otherwise, unless the professors of these schools are more willing to work for love than for money. In a few instances this may be so, but in the great majority of cases it is contrary to all law and reason. While it does not follow that, because a thing is cheap it cannot be good, it is nevertheless admitted the world over that a high price is a certain guarantee for excellence. The burden of proof regarding any uniform relation between extra quality and cheapness is upon the one who advocates such a doctrine. Generally speaking, the best argument in favor of cheapness is cheapness itself. It is, in fact, a central idea, around which all questions of value received must necessarily revolve. Price and quality always bear such a direct relation to each other that it is impossible to separate them. If a particular commodity has a recognized market value, it always commands a market price. This is a law of economy, any exception to which is always looked upon with suspicion by the buyer. If any question comes up regarding the extra quality of a cheap article, something more of proof is required of the relation of the one to the other than the mere assertion of the interested parties. While we repeat that cheap colleges may give good courses of instruction, there is no very good reason for supposing that the students get more than their money's worth. No teacher cares to do good work for the mere credit of the thing, or because he knows he is sparsely paid for his services. The most charitable feelings toward the poor struggling students can hardly explain such pure disinter-

estedness in his behalf. On the contrary, if the student gets a fair return for his outlay, the conscience of the teacher should be, and we doubt not is, satisfied. If we admit the soundness of these views, we are irresistibly driven to the conclusion that cheap education cannot be so good as that which commands a higher price.

We think we give the requisite force to this statement when we assert that the Faculties of the higher-priced schools fairly earn their money and give ample satisfaction to their patrons. The continued prosperity of these schools is explained in no other way. The adoption of the high prices of medical education, to which our correspondent refers, was a matter of necessity rather than of choice. In view of the rivalry between these schools, the question concerning educational advantages was of first importance; the grade could not be lowered, and the fees had to be raised to correspond. That there are so many students who are willing to pay these fees, quite conclusively shows that they appreciate extra advantages. It is so much to the interest of the larger schools to obtain all the students they can, that it would be a suicidal policy on their part to charge high fees when smaller fees would answer the purpose.

At the risk of still further taking issue with our critic, we cannot see why students who have enjoyed the extra advantages of large metropolitan schools should not be better qualified to perform professional duties than their less fortunate brothers. If his assumptions are based on fact, then our case falls to the ground, and cheap medical education is triumphant. It is, after all, the real test of the quality of the article, and completely overthrows the suspicions associated with its cheapness. In the absence, however, of anything but mere assertions, we are in doubt in regard to the soundness of his views. As far as the title of M.D. may go, every graduate is on a par; but we seriously question if the majority of the students educated in the cheap colleges could pass satisfactory examinations in this city, Boston, or Philadelphia. We say thus much in no disparagement to the average struggling student, as we believe he does the best he can under the circumstances. It is not so much a reflection upon his capabilities of learning as upon the previous advantages he may have enjoyed. It seems almost absurd to suppose that the facilities for medical education in a medical centre are not greater than those in some obscure or inland town. The difference in the advantage of each are so well established that the statement of our correspondent is almost presumptuous. Not only is this difference acknowledged by students and practitioners, but by professors themselves. The classes in our leading schools are not made up entirely of students. There is a plentiful sprinkling of old practitioners who come from different parts of the country to "brush up" by attending lectures here, and not a few professors in some of the outside col-

leges are to be found with note-book in hand, the most earnest and interested of students. This is as it should be, and proves that these rural teachers are willing to give their pupils every opportunity in their power. It is very true that the college cannot make the man, but it certainly helps a great deal. The greater the advantages, the better are the chances for the good student. In this respect the high-priced schools must excel those of lower price, not because the fees are larger, but because they enable the student to enjoy proportionately greater advantages. From this point of view we maintain that a so-called high-priced education is the best guarantee of its genuineness and excellence.

Cheap medical education, aside from its tendency to lower the standard of qualification, has a bad effect in other ways. It unquestionably persuades a great many to enter our ranks who have no business there. If we cannot prevent the rich fools from entering our colleges, we at least have the means of hindering some of the poor ones. We speak of these two classes only in reference to their mental qualifications, in which respect they are on a par. The profession can do without either, but it unfortunately has to take both. The rich fool is a necessary evil, and must be endured. Unless the cheap colleges say they will not allow him to matriculate simply because he is wealthy, they have no right to find fault. On the contrary, they widen the circle by extending equal advantages to his impecunious brother. It is in the way of preventing the latter that the higher fees are of special use. If a small fee is required, there is not much hesitation by the student on account of the extent of the pecuniary risk which he incurs. It is an inducement for the profitable investment of a small capital which no weak-minded youth can resist. Its very cheapness, compared with the value of the prize which he hopes to gain, places it on a par with a lottery speculation. Not much will be lost, but a great deal may be won. The inevitable consequence of all this is, that a host of incompetent men are actually coaxed to study medicine, who under other circumstances might never entertain the thought of so doing.

But allowing, by a stretch of the imagination, that these men may be properly qualified to enter upon their studies, we ask if it is an act of true charity to encourage them with the idea that very little money is required? A student with scanty means always has a poor chance to succeed. The question of scant money means scant time, and scant time means superficiality. Associate with these the annoyances of petty pecuniary embarrassments during student life and the all-absorbing anxiety to keep from starving after his graduation, and we can easily see that his chances for professional success are not at all promising. Still, we are informed that cheap medical education is designed to help this very class; but how it can properly and consistently

do so is not quite clear to us. Of course it will be urged that there is a want for just such men as the cheap colleges may furnish. We deny the fact. The excuse for furnishing incompetent men might have held good fifty years ago, but it does not now. There is only one necessity with such a class, and that is its suppression, and the sooner we make use of one of the many means to that end the better.

#### CONCERNING PROCEEDINGS FOR MALPRACTICE.

AN act has been recently introduced in the Legislature which is of considerable interest to all who are liable to be sued for malpractice. It provides for the filing of security for the payment of damages and costs by the plaintiff in actions or proceedings against physicians, surgeons, and dentists for damages. There is certainly a show of justice in this which it is to be hoped may be sufficiently apparent to the legislators to cause them to give their sanction to the measure. At least the physician or surgeon will not be called upon to bear the burden of every plea for malpractice which may be trumped up against him. The history of such cases fully proves that in the majority of instances of the sort the charges are unfounded, and are either made as offsets to bills for professional services, or for purposes of revenge on the part of the plaintiff, or on account of the covert connivance of some jealous professional rival. If the plaintiffs in such cases are required to give some tangible evidence of their sincerity in the matter, such suits will less commonly occur, and will be well considered before they are entered upon.

#### Reviews and Notices of Books.

**CIVIL MALPRACTICE: A Treatise on Surgical Jurisprudence, with Chapters on Skill in Diagnosis and Treatment, Prognosis in Fractures, and on Negligence.** By **MIL O. McCLELLAND, M.D.** New York: Hurd & Houghton. 1877. 8vo, pp. 554.

EVERY one engaged either in the practice of medicine or surgery is so liable to be called to legal account for alleged neglect or want of skill, that such a work as the one before us supplies a very important place. To many who have never given any study to the subject of which it treats, it will be a matter of surprise to learn how accurately the questions of mutual responsibility of physician and patient have been determined by the law. Our author has taken the greatest pains to collect in the present volume all the decisions concerning the leading suits for malpractice, and to evolve the principles upon which such decisions were founded. Naturally the questions of skill in reference to the treatment of fractures and dislocations receive a great deal of attention. In fact, the majority of suits against surgeons is in consequence of the so-called imperfect results of these cases. The abstracts of the former are exceedingly interesting, and, as they have never before been collected together in a single volume, are of the utmost value to every one who is

liable to treat this class of injuries. The same may be said of dislocations, the difficulties in the treatment of which are so liable to give dissatisfaction to the patients and their friends. The question of legal responsibility of the surgeon is one of the greatest moment, and we are satisfied that if it could be properly understood by the majority of practitioners, there would, in most cases at least, be but little ground for the plea of the plaintiff to rest upon. It is impossible even to glance at the points discussed in these decisions, as they cover a wide field of expert evidence and involve a thorough appreciation of the principles upon which any action for damages can be sustained. Suffice it to say, however, that the exercise of ordinary professional skill and of due diligence are generally all that is required of the practitioner to guard against damages. But the legal definition of what may be skill and diligence on one hand, and what may be ignorance and neglect on the other, varies greatly with different cases. It is by a careful study of such that the general legal principles upon which the distinctions are founded can be intelligently and properly appreciated. In the work before us the great variety of cases collected, with the decisions thereon, give ample opportunities for such study. But these cases are not confined to fractures or dislocations, but comprise those of the different operations in surgery and the treatment of medical cases proper which have been the subjects of malpractice suits. The author takes advantage of his opportunity by presenting some general observations upon skill in diagnosis, skill in treatment, prognosis in fractures, and negligence, which are singularly full of interesting principles and facts. Indeed, the amount of practical information contained in these chapters give the work a character for usefulness to the practitioner irrespective of the primary object of its publication. On the whole it is an admirable work, and no one who is in the habit of treating responsible or grave cases can afford to be without it. It is, in fact, just such a work as has long been needed, and we predict for it a hearty reception.

TRANSACTIONS OF THE AMERICAN MEDICAL ASSOCIATION. Vol. XXVII. Philadelphia. 1876. 8vo, pp. 715.

THIS is a larger volume than has appeared for many years, and contains more than the ordinary amount of valuable material. The addresses were admirably adapted to the purposes of the Association, and the reports of meetings of the sections surpass those of any which have previously appeared. Their accuracy of detail is such that in reading them one is enabled to be present at the meeting, and almost take part in the discussions. The Committee of Publication certainly deserve more than ordinary credit for the interesting volume which they have given the profession, and for their excellent judgment in the selection of the papers which are published. Without desiring to make invidious comparisons, and while making the statement that all the papers were creditable to their authors, we cannot resist the temptation of calling especial attention to the contributions of Dr. Sayre on "Extension and the Plaster-Paris Bandage in Pott's Disease of the Spine;" of Dr. Woodward, on "The Micrometry of Blood in Criminal Cases;" and of Dr. Adinell Hewson on "Pirogoff's Amputation."

TWENTY-FIRST ANNUAL REPORT OF THE TRUSTEES OF THE STATE LUNATIC HOSPITAL AT NORTHAMPTON, MASS. Boston, 1877.

THIS interesting state document, for such it is under the Massachusetts rule of control of public charities,

contains the usual valuable information derived from the experience and ability of Dr. Pliny Earle. He devotes many pages to a copious historical sketch of the views of numerous psychologists on the curability of insanity, and draws anything but sanguine or hopeful conclusions from the statistics of leading hospitals for the insane. Indeed, after a full discussion of the subject, he is forced reluctantly to agree with Dr. Thurnan, of the York (Eng.) Retreat, that in round numbers, of every ten persons attacked by insanity, five recover and five die, sooner or later, during the attack; of the five who recover not more than two remain well during the rest of their lives, and the other three sustain subsequent attacks, during which at least two of them die.

A TREATISE ON HERNIA, with a new Process for its Radical Cure, and Original Contributions to Operative Surgery and New Surgical Instruments. By GREENSVILLE DOWELL, M.D., Professor of Surgery in the Texas Medical College, etc., etc. Philadelphia: D. G. Brinton, 115 South Seventh Street. 1876.

THIS monograph contains a description of the various forms of hernia, the various kinds of trusses employed in palliative treatment, and the various operations which have been resorted to for producing a radical cure. The author presents his own method of operation for radical cure, and claims for it a degree of success which has not been obtained by any other surgeons. With that method the readers of THE RECORD have already been made familiar. Whether it shall prove to be the great desideratum in this class of cases remains to be determined. The number of cases in which permanent cure of hernia has been effected by operative procedure has not afforded very great encouragement to the cautious surgeon; hence, every new plan offered is looked upon with a certain degree of incredulity.

THE PREVENTIVE TREATMENT OF CALCULOUS DISEASE, AND THE USE OF SOLVENT REMEDIES. By SIR HENRY THOMPSON, F.R.C.S. Second Edition. Philadelphia: Lindsay & Blakiston. 1876.

THIS little brochure contains the practical suggestions of an acknowledged authority upon calculous disease. It is divided into two lectures; the first, on the early history and prevention of calculous disease; the second, on the treatment of stone in the bladder by solvents.

In the first lecture we have laid down a plan of treatment for the prevention of uric acid gravel which is somewhat at variance with the one more commonly employed, and consists in the use of a certain amount of blue pill, followed by mineral waters containing a goodly proportion of sulphate of soda: Friedrichshalle followed by Carlsbad. The diet must be regulated also, and the recommendation is that there should be a sparing use of alcohol, saccharine and fatty matters. The conclusion is reached in the second lecture "that there is no evidence whatever that one case in a hundred of those who have swallowed solvents for the stone has been cured of it, during all past experience down to this day." The book contains many practical suggestions regarding the diet, the use of mineral waters, the use of alkalis, injection of the bladder, etc., and is worthy of careful perusal.

THE BUFFALO MEDICAL AND SURGICAL JOURNAL N. Y., after a suspension of three months, has commenced its regular monthly issues. The present number contains many interesting articles. Drs. Julius F. Miner and Edward N. Brush are still the editors.

## Reports of Societies.

### NEW YORK PATHOLOGICAL SOCIETY.

*Stated Meeting, February 28, 1877.*

DR. E. G. JANEWAY, PRESIDENT, IN THE CHAIR.

#### LARGE FORAMEN OVALE.

DR. AUSTIN FLINT presented, on behalf of Prof. C. L. Ford, of the University of Michigan, a heart with a remarkably large foramen ovale. The specimen was removed by a student of the University from an adult dissecting-room subject. With a desire to save the lungs for study, the gentleman in question had damaged the heart somewhat, but fortunately had not injured the auricular septum. In the latter, Dr. Ford could distinctly trace the boundary of an opening two inches in one direction, and one and three-quarter inches in another direction. The right auricle was considerably dilated. The left had been cut away in the removal of the organ.

Dr. Flint remarked that as far as he knew to the contrary, this was the largest foramen ovale on record.

DR. HEITZMANN remarked that Rokitansky had recently published a work on malformations of the heart, in which cases were represented with an entire absence of the septum.

DR. FLINT also presented for Prof. Ford the heart of a deer, showing a bullet wound in its substance. The case had already been reported in the *MEDICAL RECORD* (*vid.* *MEDICAL RECORD*, vol. x., p. 173).

#### ENLARGED BRONCHOCELE—TRACHEOTOMY—DEATH.

DR. JOHN H. RIPLEY exhibited a bronchocele removed post-mortem from an adult female patient of the St. Francis Hospital. She entered the institution on the afternoon of Feb. 26th. Dr. Ripley saw her two hours afterwards. She was unable to lie down on account of severe and persistent dyspnoea, induced by the presence of a large tumor on the anterior portion of her neck. This growth extended from the upper border of the larynx down to the sternum, which it partially overlapped. It was more confined to the left than the right side, very hard to the feel, somewhat nodular, especially on the left side. In addition to this tumor there was a smaller one, which seemed to be attached by a pedicle farther to the left. The axillary and inguinal glands were slightly enlarged, but this was not the case with the lymphatics of the neck.

On percussion, it was found that dulness extended an inch and a half below the upper border of the sternum. It was inferred, on account of this dulness, that the tumor extended into the upper mediastinum, and in accordance with such a supposition all hopes of relieving the patient by removal of the tumor were given up. The urgent dyspnoea, however, called for the performance of tracheotomy. An incision was made, extending from the upper border of the larynx down to the upper margin of the sternum. The trachea was found displaced to the left. The wound was left open. The relief of the operation was only temporary, the patient dying the following afternoon.

At the autopsy, the tumor was found to have extended into the anterior mediastinum as low down as the bifurcation of the trachea, to have encircled nearly the whole of the larynx, and by pressure posteriorly to have nearly occluded the oesophagus. It should be stated in passing, that difficult deglutition was a prominent symptom. The diagnosis of sarco-

matous tumor was made before death, and was subsequently confirmed by the microscopical examination of Dr. Edel.

A point of interest in connection with the operation was the marked decrease of the tumor after the trachea was opened. There were small secondary deposits in the lungs.

DR. MASON referred in this connection to a case recently presented by Dr. Weir, in which the same operation was performed for a cancerous tumor in that locality, and in which tracheotomy afforded the patient a relief of several weeks.

#### FIBRINOUS CASTS OF THE BRONCHIAL TUBES.

DR. BEVERLEY ROBINSON presented a specimen of fibrinous casts of the bronchial tubes, which had been expectorated from a female child. The specimen was sent to him by Dr. Browne, of Syracuse, N. Y. The casts were expectorated by a female child about ten years of age. She had had an acute attack of bronchitis in September, 1876, and since that period had, at intervals of two or three days, expectorated, after a paroxysm of cough, fibrinous casts similar to those presented to the Society.

There were no physical signs of a morbid condition of lung tissue other than the fact of the presence from time to time, in the sputa, of arborescent masses of fibrin.

The health of the child remained apparently unimpaired, and, singular to relate, she was even increasing notably in strength and flesh.

DR. BRIDDON referred to the case of an officer who, during the late war, was seized with urgent dyspnoea while temporarily stopping in the city. He was summoned to the case by Drs. Budd and Holcomb, with a view of performing tracheotomy. On his arrival he was shown a fine specimen of bronchial casts previously expectorated by the patient. It was of much greater magnitude than the one presented, and was the largest specimen of the kind he had ever seen. The condition of the air-passages was quite apparent, and tracheotomy was considered by Dr. B. to be useless. The patient insisted, however, upon its performance and was gratified. He died three hours afterwards.

DR. FLINT alluded to a specimen presented some years ago by Dr. Stephen Rogers; also to two of his own.

DR. JANEWAY also referred to a case in his experience, and stated that the specimen was in the museum of the University Medical College.

#### CANCROID TUMORS OF PERINEUM REMOVED BY ELECTROLYSIS.

DR. EDEL exhibited a male patient from whose perineum he had removed by electrolysis three cancrroid tumors. The first two operations were performed in 1873, the last in 1874; since which time there has been no return of the disease. He considered the patient entirely cured. The cicatrix presented a remarkably clean and healthy appearance. The different tumors removed were also exhibited.

#### ONE OF THE POSSIBLE CAUSES OF MITRAL SYSTOLIC MURMUR.

DR. JANEWAY presented a heart illustrating one of the causes of mitral systolic murmur. It was removed from a patient who died, shortly after admission into Bellevue Hospital, from hemorrhage in the pons varolii. Dr. Peck, one of the house physicians and a very competent auscultator, on examining the patient, discovered a distinct systolic murmur at the base of the heart, which murmur was conveyed to

the left. On post-mortem examination of the heart no valvular lesions were found, but simply a small fibrous cord, which stretched itself across the cavity of the left ventricle. To the presence of this cord was, in Dr. Janeway's opinion, due the murmur heard during life. He had met with these intra-ventricular growths before, but had not, until the present case, been able to associate with them the existence of any

#### AUSCULTATORY PHENOMENA.

DR. FLINT remarked that the specimen was interesting to him for the reason that it seemed to explain an hitherto unrecognized cause for intra-ventricular murmur. He was convinced that murmurs might be caused by other than valvular disturbances. One of his pupils had called his attention to an ingenious explanation for mitral murmur when no valvular lesion existed. The explanation was, that the heart with the systole came in contact with the projecting portion of the lower lobe in such a way as to produce a murmur by forcing the air from the vesicles into the bronchial tubes.

#### ANEURISM OF ANTERIOR TIBIAL ARTERY.

DR. JANEWAY presented a specimen of aneurism of the anterior tibial, with the following history:

Wm. Daek, 47, M.; Canada; carpenter; admitted Feb. 24, 1877; always previously healthy until five years ago, when he had intermittent fever; denies syphilis. In August last had to give up work because of pain in calf of leg. This pain had been slight for three or four weeks. Had to remain in bed seven weeks, when he was able to go about and work without much pain except that of slight stiffness. The pain increased, and he was treated at a dispensary for what they called rheumatism.

Three weeks ago the pain became suddenly intense, and continued so for a day, when it became less. The leg began to swell immediately and became cold. It continued to swell until admitted to the hospital. On Feb. 23d, the foot began to turn purple, and soon after blebs appeared on its dorsal surface. On examination, the foot and leg are three times their normal size; the foot cold and purple, with some blebs upon it; the tissues of leg very tense and hard. There is some bulging of upper part of calf of leg, and pulsation of only the superficial artery could be felt over the tumor. No pulsation could be detected in either of the tibial arteries, as all the tissues were very tense. A.M. P. 115, R. 38, T. 101½; P.M. P. 120, R. 34, T. 102½.

Feb. 25th.—Under the direction of Drs. Janeway and Gouley, an incision about two inches long was made on the inner and posterior aspect of the leg, just below the knee. Through this opening dark clotted blood was removed from between the soleus and gastrocnemius muscles.

Feb. 27th.—At a consultation to-day, it was unanimously the opinion of Drs. Wood, Sayre, Mason, Crosby, Gouley, Curtis, and Smith, that the leg be amputated.

The majority favored amputation through lower third of thigh; and this operation, with lateral skin flaps, was performed by the house surgeon, Dr. Woodruff, according to Lister's antiseptic method. Carbolized catgut ligatures being used and left in wound, and flaps brought together by silver sutures.

Before operation P. 100, T. 100½.

In this case the house-surgeon, Dr. Woodruff, who has had the accompanying history of the case drawn up, alludes to my advising an incision:—

As I was passing through the ward, Dr. — asked me to look at the leg. I noticed the marked tension

of the tissues, the great swelling without pulsation, and advised the incision with an idea that the case was one of cellulitis. On leaving the hospital, and thinking over the case, it occurred to me that it was possibly a diffuse aneurism without pulsation. On returning, I found that Dr. Gouley, in whose service the case was, also advised incision, and then I re-examined the leg, finding, however, no positive proof of aneurism. The Dr., at my advice, put in an exploring-needle first, but only a little serum escaped. Then the incision was made with the result mentioned, which made me feel pretty confident that the condition was due to diffuse aneurism.

The leg, which I show by request of Drs. Gouley and Smith, in whose service the patient is, and who are unable to be present, shows an aneurism of the anterior tibial artery. I could, on dissection, not find this artery from its point of emergence, from the popliteal to a little distance on the anterior aspect of the interosseous membrane. There was an oval aperture in the side of the popliteal leading to the aneurism at the point at which I suppose the anterior tibial was given off. This was about one-third of an inch in length.

That is, that a true globular or anterior tibial fusiform aneurism occupied the part of the anterior tibial, between its origin and its passage through the interosseous membrane. That later it formed a false sacculated aneurism in this side, and still later, when the leg began to swell, burst into the space beneath the deep layer of the posterior fascia, on the side of which and in the space in the course of the peronei muscles, we found clotted and squamous blood, and also between gastrocnemius and soleus. The old aneurismal sac was filled with laminated fibrin and some more recently coagulated blood. The only cause for the obstructed circulation seemed to be due to the pressure of the enlarged aneurism on the popliteal artery, as the sac not only lay beneath it, but also curled up on its side.

Dr. Janeway also exhibited a specimen of

#### EMPHYSEMA WITH GAS IN PLEURAL CAVITY DUE TO DECOMPOSITION OF FLUID.

Male, age 32; admitted Dec. 22, 1876, for incised wound of forehead, the result of a fall on the street, during an epileptic attack.

January 9th.—It was noted that he was becoming shaky, muttering to himself with fever, etc. A hypodermic needle was inserted on the 7th in the right side, as a means of exploration, with no result. On the 13th it was again used, and a sero-sanguineous fluid withdrawn.

On the 15th, his chest was aspirated and fourteen ounces of pus withdrawn.

On the 17th, a deep redness appeared on the right side, and extended around on the back; some crepitation also existed in the tissues. Dr. Janeway examined the case on the afternoon of the 17th, and found adhesion of the upper lobe to chest wall. Pyopneumothorax, with distinct succussion sound below, and the cellulitis of the side as noted above. The gas in the tissue he supposed might come from decomposition, or from air which might have escaped from the lung; though there was no evidence of communication between the lung and the gas-holding pleural sac when he examined him.

For these notes Dr. J. acknowledged his indebtedness to the house-surgeon, Dr. Stillwell, being the abstract of a history furnished by him.

The patient died of asthenia on the 20th, at 1 A.M., and Dr. J. made the autopsy on the succeeding day.

Brain normal, with exception of a small pigmented spot in the left side of the medulla. Heart normal.

The right pleural sac showed the upper lobe adherent to the chest wall and part of the medulla. The space occupied by the rest of the lung was occupied by gas and pus; much more of latter than former. Several sloughs were found on the thickened pleura covering the lung, but no communication with lung tissue. The ribs were necrosed for about two inches from spinal column, and at this point the pleura was partially sloughy, and the tissue beneath and through this the communication existed between pleura and the cellulitis of right side. The pus had an extremely fetid odor. The left lung was somewhat congested, otherwise normal. Liver normal in size, but cirrhotic; condition granular; spleen showed evidences of former malaria; dark color, pigmented.

Kidneys appear normal; a section of the inflamed portion of right side showed the tissues infiltrated with pus.

He presented the specimen for Dr. John G. Curtis, in whose service was the patient from whom it was removed.

There were several points of interest about the case. 1st. The failure of the removal of fluid by the hypodermic syringe. This he had seen happen from the imperfection of the syringe as a suction agent, probably from the detachment of lymph, which, getting over the needle, prevented the suction force from acting. Also where adhesion of lung to the chest wall was present in different parts, from the needle entering the lung, and not the pus or serum-holding sacs. He had also seen fluid withdrawn under such circumstances, either by employing another syringe of better suction force, or else, if this be good, by introducing the needle in another site.

2d. The case was of especial interest, showing as it did an illustration of pyopneumothorax from gas developed from decomposing pus due to the sloughs in different sites. It is the second instance of pyopneumothorax which I have met due to this cause.

## Correspondence.

### CHEAP MEDICAL EDUCATION.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—I do not think you are quite just in your reply to the Columbus professor of physiology in a recent editorial, where you so unqualifiedly denounce what you term "cheap medical education." You seem to think that the *high price* of medical education furnishes a sufficient guarantee for its genuineness and excellence; and, per contra, those institutions of less pretensions in regard to price, must of necessity furnish an inferior grade of learning. Did it never occur to you that the gentlemen who give instruction to students who have purchased their tickets for \$50.00, are as competent in every particular to give such instruction as their neighbors of the \$140.00 school? Or that the hosts of M.D.'s turned out every spring from your New York colleges are not one whit better qualified to perform their duties than the far sparser number graduated from a \$50.00 Chicago house? You say the plan of cheap medical education opens the way for persons to enter the profession who, because of their ignorance, would find a proper level outside of it. If poverty and ignorance were synonymous, and wealth the standard of excellence, then, indeed, the high-priced colleges should have sway; but as they are not,

and as there are fully as many rich fools as poor ones, I maintain that as many ignoramuses get into the profession because they can wield their respectable \$140.00, as because they can "scrape up" a much smaller sum. Thus we see high prices do not keep out the unworthy ones; but do they not very often prove an effectual barrier to the worthy and diligent?

J. B. STAIR, M.D.

JUDA, WISCONSIN, March 20, 1877.

### THE CLIMATE OF NASSAU.

NASSAU, 24th February, 1877.

TO THE EDITOR OF THE MEDICAL RECORD.

I VENTURE to offer two suggestions as appendices to your valuable article on the climate of Nassau in your issue of the 10th inst., which, though they can hardly claim to be within the scope of scientific inquiry, may prove serviceable to invalids proposing to visit the island.

*First.*—It is proper to prepare the patient for the enervating effects of the climate during the first two or three weeks of his stay. The sudden transition from the cold of the North to the heat of the tropics is almost enough in itself to account for the relaxation which even healthy visitors complain of at the beginning; but the power of the sun's rays is greater than is generally supposed, a solar thermometer with blackened bulb registering 130 to 140, even in the winter months, and an ordinary thermometer placed on the grass marking 110 to 115, the range in the shade meanwhile being 70 to 75. Much disappointment is frequently felt by invalids that they not only do not rally at once upon their arrival here, but that they experience even greater lassitude than before; whereas, if they were made to comprehend beforehand that this loss of strength is only temporary, and if they came provided with such tonics as previous experience had indicated as appropriate in their special cases, the evils of unfulfilled anticipations would be avoided.

*Second.*—The changes of the wind should be fully as much an object of solicitude to the sojourner at Nassau as those of the thermometer. With a strong northerly wind a sensation of chilliness is noticeable that seems almost incompatible with the actual registered temperature, while an opposite result is to be observed with a southerly wind. In the first-named instance, too, the air is perceptibly drier than in the last named. In short, the effects are precisely similar to those consequent upon the changes of the wind at sea in temperate latitudes, and care should be taken to dress with this in view, otherwise the invalid is liable to colds and congestions, to which the condition noted in the first suggestion renders him extremely susceptible.

If the foregoing hints commend themselves to your favorable consideration I shall be glad to have them given publicity in such form as may be most convenient to you. I am tempted to offer them because, had information of this character been imparted to me before my arrival here, it would have saved me both trouble and annoyance.

Very respectfully yours,

J. D. PRINCE.

### FOREIGN BODIES IN THE NOSE.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—In the recent discussion before the Pathological Society, on the removal of a button from the nose, I see no mention of a very simple, but very

efficient, method, which has often succeeded after instruments have failed. It is merely to blow the patient's nose for him, by closing the empty nostril with your finger, and blowing suddenly and strongly into the mouth. The glottis closes spasmodically, and the whole force of your breath goes to expel the button or bean, which commonly flies out at the first effort.

This plan, which was told me by a layman, has the great advantages of exciting no terror in the child, who is perhaps always the subject, and of being readily employed at once by the parent, before delay has given opportunity for swelling and impaction. In a possible adult case, the Politzer method of inflating the tympanum might prove as serviceable, and more agreeable to the fastidious.

Yours, respectfully,

J. W.

ITHACA, N. Y., 1877.

### ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from March 18 to 24, 1877.*

RANDOLPH, Jno. F., Surgeon. Assigned to duty at Fort Trumbull, Conn. S. O. 61, Mil. Div. of the Atlantic, March 17, 1877.

WOOD, M. W., Asst. Surgeon. Assigned to duty at Cantonment Reno, Wy. T. S. O. 34, Dept. of the Platte, March 13, 1877.

GARDNER, E. F., Asst. Surgeon. Assigned to duty at Camp Hancock, Dakota T. S. O. 31, Dept. of Dakota, March 15, 1877.

ANDREWS, W. C. C., Asst. Surgeon. Assigned to duty at Fort Stevens, Oregon. S. O. 22, Dept. of the Columbia, March 7, 1877.

HANSON, A. B., Surgeon. Died March 19, 1877, at Fort Trumbull, Conn.

### Medical Items and News.

CONTAGIOUS DISEASES.—Comparative statement of cases of Contagious Disease reported to the Sanitary Bureau, Health Department, for the two weeks ending March 24, 1877.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-Spinal Meningitis.	Measles.	Diphtheria.	Small-pox.
March 17 . . . . .	2	1	85	5	8	50	1
“ 24 . . . . .	0	3	67	2	16	44	1

COMPLIMENT TO AMERICAN SURGERY.—Professor Langenbeck, of Berlin, in speaking of Dr. James R. Wood's cases of sub-periosteal resection, says that they are unequalled in surgical history. By special request the original specimens have been sent to the professor, to be presented by him at the meeting of the Medical Congress, of which he is President.

THE WOMAN'S MEDICAL COLLEGE.—The eighth annual commencement of the Woman's Medical College of the New York Infirmary took place on the evening of March 27th, at Union League Hall, which was filled to its utmost capacity by the friends of the graduates. Mr. Samuel Willets, the President of the College, con-

ducted the exercises. The stage was occupied by the Faculty and the members of the graduating class. The exercises, which were interspersed with music, consisted of the administering of the Hippocratic oath to the graduates by Prof. Emily Blackwell, the conferring of degrees by the President of the college, the awarding of prizes to Victoria Ann White and Kate Johnson Jackson, the former receiving a medal and the latter a case of surgical instruments; a valedictory address by Miss Jackson, and addresses by Rev. Dr. Howard Crosby and Prof. Mary Putnam Jacobi.

PROPHYLACTIC FOR VENEREAL DISEASE.—A subscriber writes:

“NEW YORK, March 17, 1877.

“DEAR DOCTOR:—Will you give us an idea as to how the ‘Prophylactic for Venereal Disease,’ given on p. 176 of to-day's RECORD, is to be used after being ‘filtered’? Is it to be injected into the vagina, or is the penis to be wrapped up in the mixture, or injected into the urethra? It might be used internally too without harm. If it is good for anything, let us know how to use it, and oblige.”

[The authority from which we quoted, further states that “this simple, rational, innocuous, and non-irritating lotion is to be directly applied to the virile member, upon which it forms a protecting stratum,” a sort of *boudruche à vernis*, as the French would say.—Ed.]

COLLEGE COMMENCEMENTS.—During the recent commencement season Jefferson Medical College, of Philadelphia, graduated 198; the University of Pennsylvania, Medical Department, 121; Women's Medical College, Philadelphia, 15; Buffalo Medical College, N. Y., 30; Rush Medical College, Chicago, 103; Louisville Medical College, 47; Medical Department, University of Louisville, 27. The returns are not yet complete; other colleges to be heard from.

PURPERAL FEVER AND POST-MORTEM EXAMINATIONS.—At the meeting of the New York Pathological Society, Feb. 10, 1877, Dr. F. V. WHITE asked the question whether it was safe to attend a parturient woman immediately after performing an autopsy.

Dr. JANEWAY did not think that there was any special danger in so doing, and related the following remarkable circumstance: He was called in great haste to see a case, the nature of which was not at the time explained to him. On arriving at the house he found a woman the subject of placenta prævia, with active hemorrhage. Having that afternoon made a post-mortem examination of a case of purperal peritonitis, he found himself in a dilemma, and declined to have anything to do with the case. He sent for a medical friend, who could not come. In the meantime flooding was going on, and something had to be done to save the woman's life. He was compelled to detach the placenta and allow the head to come down. The patient made a perfect recovery without an untoward symptom. He believed that there was more risk under such circumstances in attending cases of erysipelas in conjunction with obstetric practice than in making autopsies or in dissecting. In a word, the living poisons were more dangerous than those taken from the dead body.

Dr. BRIDDON concurred in the latter opinion, and stated that he had frequently attended confinements while engaged in dissecting, and without any bad results. The late Prof. Watts was actively engaged in obstetric practice during the whole time he was teaching practical anatomy.

## Original Communications.

## ON THE UNITY OR DUALITY (?) OF SYPHILIS.

By J. L. MILTON,

SENIOR SURGEON TO ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN,  
LONDON, ENGLAND.

## PART I.

A REVIEWER having done me the honor to speak of me in an American medical journal as a staunch dualist, I take the liberty of replying to his friendly challenge, and of stating my reasons for holding, though in a somewhat modified form, the opinions ascribed to me.

As a question of prognosis and treatment, I at once subscribe to the doctrine of duality. In my practice, true, multiple soft sore, auto-inoculable up to the stage of repair, and especially if accompanied by suppurating auto-inoculable bubo, has never been followed by a distinct train of secondary and tertiary affections, such as lepra, phagedenic ulceration of the throat, sarcocele, and nodes. In a very small percentage of cases I have met with some suspicious symptoms of after-disease, which seemed referable to the lesion, but never where its reproductive qualities had been tested by the lancet. Looking, then, for convenience sake, solely to the results of personal experience, I have for years past never hesitated to say, when asked the question by a patient, and when I have reproduced the soft, perforating pustule by grafting, that there would be no secondary disease, and that the case simply required proper local treatment with attention to the health. On the other hand, the true hard, papular chancre is so constantly followed by systemic disease that in the course of many years, while continually treating syphilis, I have never met but with two cases where I could quite satisfy myself that the patient had entirely escaped the consequences. As such exceptions are too rare to count for anything in matters so purely practical as the treatment of disease, the surgeon may safely say, in reply to the question which the patient is pretty sure to put, that there will almost certainly be constitutional symptoms requiring constitutional treatment.

Had, then, the revival in its altered shape of the old opinion, so ably argued for by Bassereau, Rollet, and others, borne no other fruit than that of enabling us, by its means and by the new light which their valuable labors have shed upon the subject, to lessen the uncertainty felt by surgeons on the question of prognosis, these gentlemen would still have deserved all praise. Previously, though men knew that out of every twenty cases of primary sore, a considerable number would not be succeeded by any affection of the system, they were quite at sea as to the future of any particular case. Hardness of the initial lesion was generally accepted as a sign of mischief, but here all approach to certainty ended, and no man felt sure that the very opposite condition might not be followed by results quite as grave. Matters stand now on a different footing, for although the dual theory still leaves a good deal unsettled about the border-land lying between the two kinds of sore in certain phases, it has fairly established the conclusions to be drawn from them in their typical shape. It has overthrown the dangerous precept of M. Ricord, that chancre is always inoculable up to the time of repair, and while

it confirms the teachings of experience as to the significance of hardening, shows in strong relief what mere experience never taught, the strictly local nature of the opposite condition. True, the line of fire drawn by the French dualists has been broken through, but these great salient points of their theory seem destined to last.

On the mere abstract question of identity I have never expressed an opinion, and if I do so now it is not with the intention of putting forward any positive views, but of offering, in the shape of a simple contribution, the result of my own observations and experiments. The remarks, therefore, which follow are essentially clinical, and though I am obliged to take the assailable points of argument from the writings of authorities, the answers to them are, in a great measure, drawn from the records of the case book. For my text I have chosen the observations of M. Melchier Robert, who has been pointed out by M. Ricord as the "champion zélé" of unity, to whose credit it must be said that, while observing the most enlightened tolerance towards the views of others, he strenuously and consistently upheld his own theory at a time when the dual doctrine was widely accepted, not only in France, but in most countries where medicine is studied, and when that of "one poison" might be described, without going out of the way to strain after metaphor, as fairly sinking under the attacks of so many able assailants. M. Robert's opinions may not exactly represent those of the more advanced unitists in the present day, but I think they embody all essential points.

M. Robert first reviews\* the statement made by M. Ricord, in 1854, that inoculation from soft sore had always yielded soft sore, and that the only trial of hard sore had produced hard sore, so that possibly there might be two kinds of virus. From this germ sprang the pure dualism of M. Bassereau, which regards the two poisons as distinct both in origin and nature, and that of M. Clerc, which makes the chancreoid an offshoot from chancre preceding it, being in fact nothing more nor less than the one virus theory in another shape—a discrepancy which M. Robert proposes † to settle as if it were a social or political difficulty—that is to say, by a little mental concession. He then points out ‡ that while three of the cases relied upon by M. Bassereau to prove the descent of infecting chancre from infecting chancre are of a nature to awaken suspicions in his—M. Bassereau's—mind, no attempt beyond simple allegation was made to show that chancreoid always springs from chancreoid. The dualism of M. Diday then follows, with induroïd chancre, a variety of simple sore, simple in its form, but infecting by nature.

M. Robert next shows that M. Ricord, while welcoming these new tenets, still paused before a difficulty which beset all attempts to decide the question. This difficulty was the determining whether soft chancre, "the hybrid product of a pre-existing diathesis and indurated chancre," was by nature and origin the same thing (*l'analogue*) as simple chancre. To decide this problem it would be requisite to bring together the person syphilitized previously and affected at the time with soft chancre, the person from whom the present affection was derived, and lastly, the person to whom it was transmitted. This double proof had not yet been made public at the time when M. Robert promulgated his views, and, if made public, could only complicate the question still farther, seeing

\* Nouveau Traité des Maladies Vénériennes, 1861, p. 298.

† Ibid., p. 200.

‡ Ibid., loc. citat.

that its starting-point is inherently vicious. Numerous observations, M. Robert continues, had shown that, while soft sore is transmitted unchanged from one virgin subject to another, soft chancre, developed on a person who had had syphilis, might convey to another, who had never suffered from this disease, hard sore and constitutional symptoms; but this he regards as insufficient evidence.

The next subject brought under notice is the series of theorems laid down by M. Ricord in his "Leçons sur le Chancre." These are: 1. That in virgin subjects simple chancre is transmitted as simple chancre, and 2. Hard chancre in the shape of hard chancre. 3. That in those who have had syphilis hard sore is conveyed in the form of soft sore resembling simple chancre in appearance, while (4) soft sore, emanating from syphilized patients may be communicated at one time in the guise of simple, in another under that of hard chancre; and that this difference is due to differences of origin, so that M. Ricord is, according to his paper, a dualist, which character I think he hardly sustains in his succeeding work.\* The regret, therefore, which M. Robert expresses † at finding that his master had abandoned all the teachings of experience to embrace a theory of a day's growth, was to be alleviated before many years had passed.

The special reasons for opposing the dual theory are next set forth by M. Robert in a series of cases. These are too bulky and numerous to admit of my giving them at length, and I therefore restrict myself to five of the more important, which, however, are here very briefly related. These cases are followed by thirty-one theorems, from which also I have extracted those chiefly bearing on the subject under notice. I propose to discuss these as they are given, and if, in doing so, I shall be found diverging from a strict line of argument, it is because I am to a great extent fettered by the method which M. Robert himself pursues.

1. The first case runs as follows: A man contracted chancre, succeeded by the whole train of constitutional symptoms. Four years later, while still under the influence of the venereal diathesis, he contracted a second chancre, and from this infected a young girl who had as a result multiple sores on the right larger labium, followed by multiple ganglionic enlargements in the corresponding inguinal region, succeeded in their turn by papule, impetigo, alopecia, and so on. The case, though so prominently put forward by M. Robert, has, so far as I can see, no bearing on the question of duality. It is opposed indeed to the doctrine that syphilis only occurs once in life, but as this doctrine is being continually refuted by the facts of every-day existence, it will be unnecessary to dwell longer on the point.

The second and third of M. Robert's cases, which are not to be understood as quoted here, strictly resemble the first, and he says they show that "soft chancre developed on a person who has had syphilis, may communicate hard sore followed by constitutional disease." The fact of such an inference being drawn from such premises shows how imperatively necessary caution is. It assumes that hard sore undergoes a change of this kind in syphilized persons, a fact about which I do not feel at all satisfied. Any such law is certainly not unexceptional, for hard sore appears twice in the same patient, and if it were even well established, would not bring us any nearer the mark as regards unity, seeing it would be first of all necessary to show that chaneroid, thus induced, had set up soft, perforating, auto-inoculable sore in another

person. M. Robert's cases lend a certain amount of support to the opinion that syphilis does exert an influence which may modify subsequent infection, but that is all. The strength of an argument is after all only the strength of its weakest part, and I am compelled to say that this is weak here as concerns the point aimed at.

It will be observed that the events spoken of are limited to the occurrence of a sore, either true chaneroid, or hard sore so changed as to look like it, in a person who has formerly had hard sore, the change being due to a previous attack of syphilis. I have said that I do not feel at all satisfied with the soundness of such an assumption, and my reason for doubting it is that soft sore occurs frequently enough in persons who have never had syphilis, and this even where subsequent events show they are not proof against syphilitic infection.

A gentleman attached in a lay capacity to a large hospital, but living in chambers with a patient of mine, contracted a painful soft sore which, however, was not tested by the lancet. Its appearance was in due time followed by that of a large and painful bubo. The patient fancied that he knew how to treat his case as well as any surgeon, and did so with the result of converting the bubo into a quagmire of matter, which he very cleverly opened with a knitting-needle sharpened at one end.

Nearly six years later he consulted me about a small, hard papule on the inside of the prepuce, just at the reflexion on the glans. There was no secretion from it, but I pronounced it to be syphilis, an opinion which he utterly scouted, as the sore was so different from the first; especially he remarked that it was painless, and not attended with bubo. However, he was quite satisfied when a few weeks later distinct syphilitic lepra broke out.

I mention this case, not because it presents any features of novelty, but because I had good opportunities of watching the course of both attacks. I did not indeed attend the patient professionally in the first attack. I did not see the chaneroid at all, nor the bubo till it was nearly healed; but his account was so clear that it might, I fancy, be accepted. In the first instance the patient suffered a good deal, and was laid up with the bubo; in the succeeding attack there was no pain. No secondary symptoms followed the first infection. I was in the habit of seeing the patient very frequently, at times almost daily, and often spoke to him about his complaint; yet I never heard or saw anything which led me to think he had a symptom of secondary disease. In the second attack, unmistakable after-effects showed themselves within three months from the date of the suspicious connection. How then did this difference arise? This gentleman had certainly not worn down his constitution by debauchery. He was temperate as a rule, and in his habits methodical to an extreme; his position in life was easy, so that there was no argument of wear and tear to appeal to, and he had not been laid up for a day since the last infection. It is, therefore, difficult to understand how one and the same virus should, without any visible cause, produce effects so widely different. Finally, I may remark that in the very few instances which I have seen, where the same person had hard sore twice, the second one always formed quickly. This did not happen in the case just related. In corroboration of the statement as to the more speedy evolution of the second hard sore, I venture to quote the two following cases which I watched with interest on account of the coincidence they presented.

On the 5th of December, 1873, I was consulted in the

\* Lettres sur la Syphilis.

† Op. citat., p. 303.

evening by a gentleman for a sense of uneasiness in the urethra, which he thought arose from a suspicious connection indulged in two nights previously, and which, I may add, ended in a slight discharge. He assured me this was the first time he had ever given way to any temptation of the kind for many years. On the 14th of the same month he showed me, on the right and inner side of the prepuce, which in him is rather long, nearly covering the glans, a pretty large, fully formed, papular chancre with eroded surface, which certainly seemed to have arisen from the aforesaid connection, as the patient again avowed that he had had no other. It was seated about half an inch from the free edge of the foreskin, and in the centre of the right limb, counting from back to front. This, was, he believed, the very spot where a hard chancre had formed ten years before, of which lesion, however, all traces had long disappeared. The papule was not so hard as such formations usually are. I cauterized it freely with anhydrous soda, and it healed, or rather shrank, with much greater rapidity than these spots generally do, having by the 18th so far subsided that the patient, who was very attentive at first, now came to the conclusion that it required nothing more, being "on its last legs." When I last saw him, Jan. 13, 1874, about the case of another member of his family, he told me that he was "all right again," but I had no opportunity of verifying this statement. Now, nearly six years previously I had taken leave of this gentleman, after a long and irregular attendance on his part for constitutional syphilis, the symptoms noted down by myself for this period being syphilitic pains, blotches, sore throat, and indolent bubo, dating from the chancre spoken of.

In the summer of 1866, while this gentleman was going through a sharp course of mercury, I was also treating a gentleman for copious syphilitic lepra derived a few months previously from a sore as hard as we ever see it, and for which I had myself attended him; and the singular coincidence spoken of is, that on February 2, 1874, only twenty days after I had last seen the other patient, he also consulted me for hard sore, fully formed, which dated, as nearly as I could make out, from intercourse on the 12th of January. It, too, though round in form, with sloping edges, was softer than the former, which I had particularly noticed, as had also the patient. I inoculated from it, but without any result, and the patient now reminded me that I had done the same thing with the previous sore. On the 9th of February, distinct enlargement of the inguinal glands of one side was made out, but many months later no other symptoms had followed; in referring to which the patient, who had suffered much from emissions, obstinate gleet, stricture, and bad orchitis, and whom I had cauterized both externally and internally, and had blistered on the perineum, scrotum and penis, grimly remarked that he thought he had already had "almost enough of such work," and that he must have been "a fine subject for experiments."

In all the cases that I have seen of multiple, auto-inoculable soft sore with bubo of the same character, the patient was, as regarded real syphilitic infection, a virgin subject. Judging, then, from the narrow sphere of one person's observation, I feel bound to scrutinize with caution histories of chancreoid after chancre. I do not deny such an occurrence, but I distinctly say that I have never met with it, neither have I read a case without some valuable point. In some degree this immunity may be due to the fact that a man who has gone through the ordeal of secondary, and perhaps tertiary disease, exposes him-

self less to contagion, and is more careful in the way of washing and cauterization, than an inexperienced person might be; in part, to the possibly lower infecting power of chancreoid. The latter suggestion may appear fanciful, and I have no evidence to support it beyond this, that, in the cases I have noted down, where these means had been put in force and where yet infection followed, the result was always a hard sore. Be the explanation, however, what it may, the rarity of chancreoid after chancre remains in my practice as I have put it.

From what has now been said the reader will see that I utterly reject the doctrine of soft sore being in any way due to a foregoing attack of syphilis. The latter may have the power of so modifying the constitution that a sore which, in a virgin subject, would have run the usual course of chancre, now takes on the look of chancreoid, but I have seen nothing that proves it, and a good deal that makes me doubt the fact. In many persons a certain amount of deterioration in the tissues, temporary or permanent, ensues under the combined influence of syphilis and mercury, such as a weak, irritable state of the nervous system, deposit of pigment, superficial ulceration of mucous membranes, which I need not touch upon generally, but which locally manifests itself in two classes of symptoms the reverse of chancreoid. One of these, often prominent, is a disposition in the site of the primary sore to take on hardening again, sometimes after a lapse of years; another, not so well marked, in parts abraded during suspicious intercourse, to assume an appearance like that of impending superficial sloughing or phagedæna, or perhaps hard chancreous abrasion; a problem left unsolved, owing to the free use which has almost always been made of caustic. I have cauterized a patient for as many as five attacks of this kind within five years. Inoculation from them has, in my hands, always yielded negative results.

But I believe there is good reason to infer that original difference of constitution, in some persons, so modifies the course of events, that a sore which would naturally have been hard runs its course without taking on the characteristic induration, and that this fact, if fact it be, is the key to the enigma. For the purpose of exemplifying this position, I select two cases where this modified chancre appeared in parts often exhibiting the most characteristic forms of induration: the thick, hard, defined circular welt, and the parchment hardening.

Several years ago, in a paper read before the Medical Society of London, I mentioned the particulars of a case where severe constitutional disease followed a small sore seated on the neck of the glans and adjoining part of the prepuce. The patient, a strong, and, according to his account, healthy man, but of an earthy look, and an unusually sluggish temperament, was under my care for stricture at the time he contracted the sore. It was not larger than a very small split pea, oval, shallow, and so free from induration that I could not believe it to be chancre. It looked almost as if a small strip of mucous membrane had been torn or dissected off, and healed without much suppuration, yet it was quickly followed by formidable crusted eruption on the scalp, severe iritis, and abscesses round the rectum, at which stage I lost sight of the patient. Somewhat similar narratives are given by Mathias, Robert, etc.

Perhaps it will be said that this was, after all, merely common chancreoid and secondary disease. To this view there are strong objections. The sore, though soft, was solitary and painless; it never took on any of the signs of inflammation; it was favorably seated

for inoculating the opposite surface, yet it did not do so; it produced no painful swelling of the groin, and it suppurated very scantily.

(To be Continued.)

## ON THE THERAPEUTICAL USES OF SALICYLIC ACID AND ITS SALTS.

By S. HENRY DESSAU, M.D.,

ONE OF THE DISTRICT PHYSICIANS TO THE N. Y. DISPENSARY, AND ONE OF THE PHYSICIANS TO THE OUT DOOR DEPARTMENT OF THE NEW YORK FOUNDLING ASYLUM.

SALICYLIC Acid, the newest febrifuge, also the newest therapeutical agent, has proved itself, in the hands of competent high authorities, of such unquestionable value in the treatment of disease, that it has rapidly and justly taken a high place, and, it is safely predicted, a permanent one, in our Pharmacopœia. Although it is not quite two years since it was first brought to the notice of the profession by Dr. Butt, of Basle, as an internal remedy, almost every number of a medical journal already contains an article upon the virtues of salicylic acid. This is as it should be; and as I have had fair opportunities to test the value of the new agent in a large number of dispensary patients treated at the bedside, I regard the contribution of my experience with, and judgment upon, the new remedy of sufficient interest to the medical profession to warrant me in presenting this paper for publication.

I have employed the salicylic acid since the 13th December, 1875, and have up to date (March 16th) used it in 77 cases, including the following diseases:

*Articular Rheumatism.*—All cases of this painful affection, 34 in number, have been treated with the salicylic acid, either pure or dissolved in carbonate of soda, since April, 1876. All were speedily benefited, and the majority relieved in a much shorter time than by any other remedy I have used. The first case of this disease in which I employed the salicylic acid was that of a man 37 years of age, who had almost every joint of his four limbs affected. It was his first attack. He had been sick about two days. I gave him 60 grains of the pure acid mixed with molasses at one dose, at about noon time, and the next morning I found him entirely free from pain and any swelling in the joints. He said he felt somewhat "stiff." He was kept in bed for several days more, when the pains not returning, he was allowed to leave his bed as cured. Since then I have not given such heroic doses in articular rheumatism, having found that smaller doses, hourly repeated, are of equal service. Neither do I now employ the pure acid, having found that it frequently produced irritation of the alimentary canal in the form of vomiting or pain in the intestines. I now use a solution of 30 grains to the ounce, dissolved with the aid of equal parts of the carbonate of soda, and flavored with some of the essential oils. According to Stricker, a chemically pure preparation of the acid is completely soluble in water and alcohol. This preparation is obtained by repeated crystallization. It is no doubt difficult to be obtained in this country. Of the before-mentioned solution I give a tablespoonful every hour, equal to 15 grains, until there is relief from pain or the patient complains of buzzing in the ears, when it is decreased to every two or three hours. The longest time that any of the 34 cases have remained under treatment for the same attack was three weeks. This was in only one case—an old toper. In the vast majority of the cases they were able to attend to their daily avocation in one week's time. In three of the cases there were relapses, which were slower in succumbing to the treat-

ment than the original attacks. In none of the cases were there any cardiac complications, at least of recent origin.

In this connection, it may be interesting to refer to an article by Dr. C. W. Brown, entitled, "Analysis of 106 Cases of Rheumatism treated with Salicylic Acid" (*Boston Medical and Surgical Journal*, Feb. 8, 1877), which contains some highly valuable statistics regarding this subject: "The average time for relief was 1.46 days; to complete cessation of pain, 2.85 days. The average amount of acid taken to produce relief was 1.54 grains; amount required to produce complete relief from pain and mobility of the joints, 531.22 grs. to each patient. Average time during which the acid was taken by each patient, 6.22 days; average number of days in hospital, 18. Two cases died of cardiac complications, developed before treatment began; 18 cases had one relapse, 3 had 2, and 1 had 5 relapses. The heart became affected while under treatment in 4.76 per cent. in cases where the complication was especially looked for. The acid was given in pill form,  $3\frac{1}{2}$  grs. each, made with honey or molasses, in doses of 10 grains hourly repeated until relief was given, when it was reduced to every 2 or 3 hours."

When I compare the salicylic acid treatment of acute articular rheumatism with the alkaline, the blistering, the muriated tincture of iron, the ammonia or the colchicum treatment, all of which I have fairly tested, I unhesitatingly give the preference for speedy and decided success to the first named. It cannot be doubted in my own mind that salicylic acid is destined to supersede all other remedies in the treatment of acute articular rheumatism.

*Diphtheria.*—I have treated 14 cases of this disease with the salicylic acid, 3 of which died. In one of the fatal cases, the expectant treatment was followed up to the third day of the disease, upon the suggestion of one of the most prominent and highly-honored members of the profession in this city. The symptoms in the meanwhile became so alarming that my conscience would not allow me to dally further with the case. I then gave the salicylic acid in powder form in small doses repeated every two hours. The stomach soon became so irritable that neither the acid nor food could be retained, and I then gave the acid in solution, but with no better result. Death took place on the 10th day of the disease. In a second one of the fatal cases, the disease had existed in a severe form for five days before I was called in. I gave  $7\frac{1}{2}$  grs. of the acid in powder every 2 hours, which was well retained, and afterwards about 5 grs. in solution as often repeated, but death took place on the 9th day of the disease. In the third fatal case I was not called in until the day before death took place, which was the 8th or 9th day of the disease. All of these cases died from exhaustion. Every case of this terrible enemy of infantile life, that I have seen in the commencement of its approach and fought with the salicylic acid, has terminated in a victory for the treatment. I do not confound cases of diphtheroid pharyngitis with true diphtheria in stating my cases, as I will show further on in this paper. I have treated numerous other cases of diphtheria at the New York Dispensary with the salicylic acid with a like favorable result, when seen in the early stages of the disease. In the light of recent theories as to the nature of the cause of diphtheria, advanced by various German authorities, namely, the germ theory, it would appear that salicylic acid is the scientific remedy for this disease. Letzerich has demonstrated that the movements of bacteria and micrococci, fungi obtained from the urine of children suffering from diphtheria, were ar-

rested by a few drops of a weak solution of the salicylic acid, and also destroyed by a stronger solution, after an interval of five months. The antiseptic properties of the salicylic acid in surgical practice are beyond question. The salicylate of soda, however, has little or no antizymotic power locally applied, yet when given internally it acts with the same effect as the acid, with the advantage of not disturbing the stomach nor intestines. Professor Binz, of Bonn, explains this apparent anomaly by demonstrating that the carbonic acid gas, derived from the destruction of body tissues, and contained in the blood, has the power to set free the salicylic acid contained in the salicylate of soda. Binz concludes that this change does not necessarily take place in the blood, but in the acid-producing tissues, such as the glandular organs and lymphatics. He asserts that salicylate of soda within the organism has a power to paralyze the development of bacteria, the supposed disease-producing ferment or *materies morbi* of specific fevers, greater than that of either carbonic acid, quinine, boracic acid, or alcohol, and almost one-third as great as that of the free salicylic acid. Salicylic acid remains in the blood for a considerable length of time, and is given off again, partially, in an unchanged condition.

**Erysipelas.**—In this disease, especially affecting the head and face, I have used the salicylic acid in light cases. All were of a severe form and had existed from two to eight days. In all of the cases the cure was rapid and permanent, an improvement being observed in twenty-four hours. The cure was generally complete in from two to four days, no extension of the disease having taken place after treatment was commenced.

The salicylic acid, no doubt, destroys the germ ferment upon which the production of erysipelas depends.

**Scarlatina.**—Eight cases of this disease have been treated with the salicylic acid, with one death, which took place at the end of the third week, from pulmonary oedema. No acid had been taken in this case for two weeks previous to the accession of the pulmonary complication. The remaining cases made favorable recoveries, one being a severe case complicated with diphtheria. I cannot say that recovery was in any way hastened in any of these cases, but the fever was kept at a minimum which certainly added greatly to the comfort of the little patients, besides preventing any of those mischievous complications that almost always attend a high febrile action in scarlatina. The remedy was not administered as actively as it was in the treatment of rheumatism or erysipelas, otherwise a different result as to duration might have been observed. I shall make further investigations in this direction.

**Typhoid Fever.**—Seven cases of typhoid fever were either partially or entirely treated with the salicylic acid. These were all but one, in children under fourteen years of age. In one case, seven years of age, treatment with the salicylic acid was begun on the seventh day of the disease with seven and a half grain doses in powder every hour. On the eleventh day of the disease the temperature in the rectum at noon being  $104\frac{3}{4}$ ° F. the dose was increased to ten grains every hour. The temperature was normal on the thirteenth day. In another case, fourteen years of age, attended with a profuse eruption and palpable spleen, temperature  $103\frac{1}{2}$ ° F., treatment was commenced on the eighth day with forty grains of the salicylic acid in powder mixed with molasses, taken at one dose in the forenoon. The temperature was reduced, and no more of the acid was given until the tenth day, when it was resumed in fifteen-grain doses every two hours. There was no rise of temperature after the twelfth day. All of the other cases, but

one, which was sent to the hospital after the second day of treatment, made favorable recoveries, but the duration of the fever was in no material degree shortened. This was probably due to the manner of administering the remedy, as small hourly doses were given. I am satisfied that Dr. Ewald's statement (*London Practitioner*, March, 1876), that the minimum dose of the acid required to reduce the temperature effectually in typhoid fever (for an adult), seventy-seven grains at one dose given at midday is in general terms correct. The entire paper of Dr. Ewald in the journal mentioned is highly interesting.

**Diphtheroid Pharyngitis.**—This term is applied by me to a severe form of pharyngitis, sometimes attended with some enlargement of the tonsils, and small exudative deposits, opalescent in character, upon the tonsils. There is high febrile action, great depression of energy, and intense pain in the pharynx upon swallowing. I have met with numerous cases of pharyngitis of this nature during the prevalence of diphtheria. Three cases of this description were treated with a solution (1 to 300) as a gargle, with instructions to swallow a part of it before spitting it out.

All three of the cases were well in less than two days.

The beneficial effect of the salicylic acid may be explained in these cases by the suggestions of Mr. J. A. Erskine Stewart (*Edinburgh Medical Journal*, Nov., 1876), who regards salicylic acid as an antiseptic, deodorizer, and *astringent*, and that it produces a specific action on the mucous membrane of the mouth, nose, and throat.

Of the remaining three cases in which the salicylic acid has been used by me, two were cases of *puerperal septicaemia* and one *diphtheritic stomatitis*. In the former the fever was decidedly reduced, and all pain from the abdomen disappeared after administering for two or three days the acid in solution in fifteen-grain doses hourly repeated. In the last-mentioned case, a child three and a half years old, the acid was used as a wash with quick success.

As the salicylate of soda has the same happy effect in the treatment of specific diseases as the pure acid, and as it has the advantage of being readily soluble in water, it will no doubt take the place of the acid as a more elegant preparation. I have lately used this salt altogether, prepared offhand in the form of the solution mentioned under the head of articular rheumatism. The only objection to it in this shape is, that it turns dark upon standing for any length of time. Amongst some of the physiological symptoms produced by the acid and observed by various writers, are nausea, vomiting, burning in stomach, pain in bowels, headache, ringing or buzzing in the ears, deafness, numbness and prickling, loud, deep, and sighing respiration, strange restlessness, gradually increasing to delirium, not unlike that of delirium tremens; involuntary evacuation of urine and feces, slow, laboring pulse, and olive-green color of urine. To these symptoms I may add dizziness and a slight bleeding from the throat, which occurred in one of my cases after using the pure acid.

81 VARICK ST.

PATHOLOGICAL TRANSACTIONS OF THE CHICAGO MEDICAL SOCIETY (Number 2) contains a description of the following cases:

Epithelioma of Hand, by Dr. T. P. Seeley; Cerebral Embolism and Thrombosis, by Prof. Henry M. Lyman; Hydatidiform Degeneration of the Chorion, by Dr. C. W. Earle; and Tuberculosis in the Lungs of a Canary Bird, by Dr. I. N. Danforth.

## Reports of Hospitals.

### THE UNIVERSITY HOSPITAL, PHILADELPHIA.

#### NOTES OF PRACTICE AND PECULIARITIES OF TREATMENT.

##### GOITRE.

WITHIN the past eighteen months, some twenty-five cases of this very interesting disease have come under the notice of Dr. Roland Curtin, Chief of the Medical Dispensary staff. Twenty-four out of the twenty-five have occurred in women, and in most cases have been intimately connected with some uterine trouble. The successful mode of treatment has been by hypodermic injections of from six to ten minims of a solution containing ninety-six grains of ergotina to the ounce of distilled water. The injection is repeated two or three times a week, for the space of from four to six months, when the gland becomes thoroughly hardened. The gland begins to shrivel with the stoppage of the injections, and very soon returns to its normal size. Ergotina is of no value in bronchocele, but only in cases of simple enlargement of thyroid gland. The injection is attended with very little pain, which pain is generally local, or referable to the origin of the sterno-cleido-mastoid muscle.

##### TENIA.

Tape-worms have been completely removed, head and all, by large electuaries of pumpkin-seeds followed by kamela, in doses at first large and then gradually lessened to three grains before meals. The diet during the early active treatment is of course exceedingly restricted.

##### PARACENTESIS.

Cases of this kind are cured by injections of from one to three drachms of Lugol's solution through the drainage tube.

The obstetrical wards are under the charge of Prof. Wm. M. Goodell.

##### ANEMIA AND CHLOROSIS.

Dr. Goodell believes in the tonic properties of corrosive sublimate used in connection with arsenic in the treatment of anemia and chlorosis.

The following prescriptions embody his practice in these diseases.

B. Hydrarg. Chloridi Corrosiv. ....	gr. i.
Liq. Chlo. Arsenitis. ....	f ʒ ss.
Mis. Ferri Chlo. } each. ....	f ʒ ij.
Acid. Muriat. Dil. }	f ʒ ij.
Syrupi. ....	f ʒ iij.
Aq. q. s. ad. ....	f ʒ vi.

S. One tablespoon to be given after each meal. The treatment must not be continued more than three weeks at a time.

The Doctor also uses Blot's pill as prescribed by Dr. Niemeyer.

R. Pulv. Ferri Sulph. ....	ʒ ij.
Potas. Carb. Puræ. ....	ʒ ij.
Syrup. Acac. q. s.	
M. et in pilulas xlviiii., divide (48).	

S. To be given daily in doses increasing until three pills are taken after each meal, which gives the large amount of gr. 22½ of the dried sulphate of iron per diem. Dr. Goodell has found all statements made by Dr. Niemeyer with regard to these pills true.

##### DYSMENORRHOEA FROM STENOSIS AND FLEXION.

Dr. Goodell very rarely incises the cervix uteri in these cases. By placing the patient under ether, and by using very powerful dilators, whose blades do not feather, he finds that it is rarely needful to use the knife. He has operated upon many cases of this kind before the class during the winter session just past with success.

##### SUBINVOLUTION OF UTERUS.

Sponge-tents are introduced in this affection and followed by the intra-uterine application of *fuming* nitric acid, applied on cotton wrapped around an aluminium sound.

##### OPERATION FOR OVARIAN CYST.

An ovarian cyst was removed per vaginam from a girl of twenty-four, in the Obstetrical Clinic, last week. This is the *ninth* time that the operation has been performed. The particulars are as follows. The tumor filled Douglas's pouch and could not be pushed up into the abdominal cavity. It so flattened the urethra that the bladder could not be emptied without a catheter. The tumor was found on examination to be adherent to the womb, which was so flattened out as to measure five inches in length. The girl was put in the position for the operation of lithotomy, which is Dr. Goodell's favorite position in operations for vesico-vaginal fistula. An incision was made, and about two quarts of exceedingly fetid pus were withdrawn from the cyst, which was with great difficulty subsequently brought outside—many adhesions needing to be broken. The cyst was now found to have no pedicle, and was firmly adherent to the whole fundus of the uterus. As a ligature could not be thrown above the cyst, the left broad ligament was transixed just above the cyst, and a double ligature tied on each side of the base of the tumor. The operation was performed at an early period in the progress of the case on account of the pressure, troubles, and very serious septicæmic symptoms which had arisen. The temperature before the operation was 102½°, and the pulse very feeble and beating at 125. Since the operation, the temperature has been under 99°, and the patient gives promise of great reduction in pulse rate.

##### SPINAL ACCESSORY SPASM.

Dr. H. C. Wood, Clinical Professor of Nervous Diseases, has lately had under treatment two cases of the above-mentioned nervous affection. European authorities state that this disease is incurable. Dr. Wood succeeded in curing one case—the other is still under treatment. In the first case the spasm was tonic in its nature, the head being drawn down to its fullest extent, and maintained in that position. The spasm, in this instance, was dependent on an inflammation near the origin of the phrenic nerve. The treatment was by hot irons over the nape of the neck, and over the contracted muscle. The heat used was intense, and only lightly applied, so as not to produce a very deep eschar. Iodide of potassium was administered in doses small at first, and gradually increased to the production of *iodism*. The case was completely cured in the course of a few months; the man has since been able to perform active work. The spasm has recurred only twice, and has in both cases been entirely arrested by the use of hot irons, which, according to patient, did not cause as much pain as a blister.

In the second case the spasms were clonic—sometimes the man was free for a few hours, then he would again have thirty or forty spasms in a minute. The

spasm was functional, and allied in its nature to hysteria, though in a man. It implicated the phrenic nerve and the diaphragm. There was a spot over the spleen, and one over the hepatic region; touching either of these spots produced violent spasms. The second case was treated with hot irons, without much success, though they were very freely used. Nitrite of amyl cured temporarily. Strychnia, injected hypodermically and *homoeopathically*, decidedly aggravated the case. The man is still under treatment, and very excellent results are being obtained by the injection of small but increasing doses of atropia directly into the muscle. Large doses of arsenic with iron and the bitter tonics are also being used.

## CHOREA.

Da Costa's bromide of iron treatment for this disease has been given a fair trial at this hospital, and under Prof. Wood's supervision, and has utterly failed. In a limited number of cases etherization of the spine was tried with but poor success. Chloral, particularly in conjunction with bromide of potassium, is of great value in obstinate cases. The best results are obtained, however, by the use of iron, tonics, and the fluid extract of *cimicifuga*.

Several cases of interest have transpired lately in the surgical wards of the hospital, which are under the charge of Prof. Hayes Agnew, and Dr. Chas. Hunter.

## HERNIA.

Dr. Chas. Hunter has performed Dr. Dowel's operation for hernia in three cases—twice with positive success. The third case failed through the intervention of a visitor who displaced one of the pins, so that it could not be returned. The operation, first suggested by Dr. Dowel, of Texas, is well known to the profession.

## CURVATURE OF SPINE.

Dr. Henry Wharton, one of the resident physicians, has made a very valuable suggestion in connection with the treatment of this disease. In the suspension of a child for curvature of the spine, instead of using the head sling, a cord is attached to the centre of the crosses over the top of the head of Barton's bandage. This simplifies the apparatus, and is less terrifying to the child.

## ULCERS.

Dr. Hunter some time ago introduced the use of oxide of zinc as a protective in ulcers. This compound is smeared around the edges of an ulcer before applying the adhesive strips, and so prevents excoriation of the skin. The oxide of zinc is used entirely at the Pennsylvania and University Hospitals.

## FRACTURE OF THE PATELLA.

Fractured patellæ are treated altogether here by Dr. Agnew's splint. This consists of a flat posterior splint, with an eminence for the popliteal space, and with four rollers screwing in at the sides, two above and two below. Adhesive strips coming down on each side from above the broken bone are fastened to the lower rollers and screwed tight, and corresponding strips from below are secured in like manner to the two upper rollers. The fragments are thus securely brought together. The whole leg is then bandaged. This mode of treatment has given most excellent results.

Dr. Chas. Hunter has lately invented a more simple apparatus for the treatment of these fractures, and

has used it in one case very successfully. Extension is made by adhesive strips on each side of the leg, adherent from the groin to just above the seat of fracture. A weight is attached to the free ends of these strips, at the bottom of the bed. The whole leg is then tightly bandaged with figure-of-eight turns round the knee. This method will at once adapt itself to the necessities of country practitioners, by reason of its great simplicity.

## Progress of Medical Science.

ON THE TREATMENT OF CHOREA.—Dr. Howship Dickinson maintains that chorea is primarily a nervous and not a vascular disease; that it has its rise in the nervous centres, where the first visible, though not necessarily the first actual change is vascular distention, closely followed by extravasation and the several tissue changes which congestion and extravasation produce. He believes that the special treatment of the disease must be neurotic, although general treatment is often more valuable than special. In severe and acute cases, where there is danger of exhaustion from loss of sleep and incessant movement, he advises liberal feeding, stimulants, and the bromides, opium or chloral, to produce sleep. The movements, if violent, must be restrained to prevent exhaustion, and also the excoriations and sores they sometimes produce. Anything which causes alarm or distress must be avoided. The bowels are to be kept open by an occasional purge. With regard to the special treatment, antimony controls the jactitation more quickly than any other drug, but it must be given in large doses to be effective, and so used it adds to the prostration. Zinc stands next in order of efficiency. It must be given in large doses to begin with; a grain of the sulphate should be given three times a day, or oftener in severe cases, and a grain added to each dose every day, till the dose amounts to from fourteen to twenty-six grains. When given in this way it does not cause sickness, but simply lessens the jactitation. In one case Mr. Dickinson gave forty-five grains three times a day. The zinc passes off by the bowels, and can be recovered from the feces, but no trace of it can be detected in the urine. It seems to be followed by anemia in some cases, and hence it is often advisable to combine it with the sulphate of iron. When the chorea subsides, the zinc should be gradually withdrawn, and the iron continued alone or with quinine. In the slighter and more chronic forms of chorea, the remedies that have proved most beneficial are iron, strychnia, and arsenic; the iron may be combined with one of the others. The iron and strychnia may well be given in the form of bromide. Where chorea is mixed with hysteria, as in young girls, electricity and shower-baths are useful, but they would do harm in simple chorea. Calisthenics and dancing seem sometimes to do good. General tonics and change of air are useful in the smaller shapes and the lingering remains of chorea.—*The Lancet*, January 6, 1877.

CEREBRAL LOCALIZATIONS.—M. Charcot terminated his course of clinical lectures on the diseases of the nervous system, at the *Salpêtrière*, with an account of cerebral localizations, the object at present of his special investigations. He thinks that accurate clinical observations will prove to be of much greater value than experimental investigations in dispelling the obscurity that still envelops, to a great extent, the

physiology and pathology of the brain. While admitting the value of experimentation, he points to the fact that removal or destruction of recognized motor centres in the brains of animals is followed by but slight and transitory paralytic phenomena. The brains of dogs, rabbits, and guinea-pigs, like those of infants under two months of age, seem to have little connection with the peripheral nervous system.

With regard to the localizations in the cortex, the motor zone is known to comprise essentially the ascending frontal and ascending parietal convolutions, which are separated from one another by the fissure of Rolando. A sufficiently extensive lesion of the upper two-thirds of one or both of these convolutions causes a hemiplegia of the opposite side, which is distinguished from a central hemiplegia by the absence of anesthesia. When it is attended by facial paralysis the lesion has surpassed the above limits, and when attended by aphasia it has extended to the third frontal convolution of the left hemisphere. Ferrier's observations indicate that this region may be subdivided into different excito-motor territories corresponding to the movements of the arm, the leg, the face, etc. The localization of some of these territories has already been settled by clinical observations.

Another set of lesions, instead of destroying the nervous elements, produce irritation of the cortical substance. This irritation is revealed by convulsions—at first partial, limited, for instance, to a single limb, but tending subsequently to become general. Syphilis is unquestionably the most frequent cause of these phenomena of incomplete epilepsy; when the existence of this specific cause is discovered, an energetic course of treatment must be promptly adopted, because, if left to itself or insufficiently treated, the cerebral lesion will lead to destruction of the nervous substance. M. Charcot prescribes mercurial frictions over a large surface, so as rapidly to produce salivation, and at the same time gives iodide of potassium in as large doses as can be borne. At the end of eight days the treatment is stopped; but if the epileptiform phenomena are not sufficiently modified, it is resumed after an interval of a few days. In this way M. Charcot has cured several cases.

A lesion of the conducting fibres that unite the motor cortical region with the spinal cord of course produces the same phenomena as a lesion of the cortex itself. *Intra vitam*, it may be impossible to differentiate the two. A lesion of the cortex may be attended secondarily by descending degenerations that can be traced into the peduncle, the medulla, and even into the spinal cord itself. The localizations in the centre of the brain may be deduced from those of the cortex; the symptoms will depend upon the bands of conducting fibres that are involved. Observation has shown that the lesion which causes a permanent hemiplegia with secondary degeneration is located in the anterior two-thirds of the capsula interna, the fibres of which unite the motor cortical zone with the peduncles; and on the other hand, that the lesion which causes hemianesthesia is located in the posterior third of the same capsula interna. The fibres of this part are directed towards a part of the cortex which seems to belong to the occipital lobe; this is the sensitive zone, but it is still little known. Cerebral hemianesthesia is sometimes accompanied by hemichorea. The frequent coincidence of the two affections shows that they depend upon lesions of neighboring parts; it is, in fact, very probable that hemichorea is due to a lesion of the posterior fibres of the capsula interna. We do not yet know to what

part of the cortex these fibres correspond. Cerebral hemianesthesia does not differ in any respect from hysterical hemianesthesia; hence, it is allowable to hold that the still unknown lesion of the latter is also located in the sensitive cortical zone. Hemichorea most frequently follows an attack of apoplexy; sometimes it precedes an attack, and in rare cases is developed slowly and independently. It may occur, with or without hemianesthesia, in children as well as in adults. In two of M. Charcot's cases the instability of the movements was developed during childhood.—*Gazette Medicale de Paris*, Jan. 6, 1877.

**STRUCTURE OF THE CELL-NUCLEUS.**—The last number of the *Archiv für Mikroskopische Anatomie* contains a paper by Fleming, in which he maintains that the reticular arrangement observed in the cell-nucleus is a vital appearance, and not a post-mortem change. Prof. Langhans, of Berne, however, has demonstrated that this reticulation is a post-mortem process in at least one variety of cells. When the cells of a fresh *Decidua serotina* (human) are examined in the warm blood serum of a recently killed animal, the nuclei are seen to be sharply defined against the protoplasm, shining and perfectly homogeneous, no traces of nucleoli or granules being discoverable. After a varying period of time—or immediately, if water or some other reagent be added—the entire mass of a nucleus divides into two substances, one of which refracts light strongly, and the other only slightly; the former is arranged in the form of a network, and the latter is collected in the interspaces. The septa of the network are very delicate, and at first of equal thickness throughout the entire nucleus; externally, they are continuous with the thin boundary layer of the nucleus—"the nuclear membrane"—which consists of the same strongly-refracting substance. This change does not cause any alteration in the size of the nucleus. In the protoplasm the reticular appearance lasts for hours, and may even often be discovered in hardened preparations, but in the nucleus the picture rapidly changes. The vacuoles or interspaces become larger, the septa become thinner, and finally rupture, and the substance of which the septa and their nodular points is composed flows together, so that finally the strongly-refracting substance is collected into one, two, or three brilliant, more or less centrally located nodules (nucleoli), while the remaining mass of the nucleus is composed of the clear substance of low refracting power. The latter may be clouded in consequence of the action of reagents, or of decomposition, and may contain a granular precipitate. The entire process consumes only a few minutes, and in consequence of the great difference in the refracting power of the two substances, it is easily watched in first specimens. Both substances are fluids. For some unknown reasons, the reticulum sometimes remains unchanged for a long time; in other cases the vacuoles near the periphery enlarge and communicate, while the central part of the reticulum persists as long as the observation is continued. No nucleoli are then produced. \*

Hence, we have to deal here with a post-mortem change, a separation of the originally homogeneous nucleus into the "nuclear fluid," and the proper "nuclear substance," *i. e.*, nuclear membrane and nucleoli. In spite of numerous investigations, Prof. Langhans was never able to demonstrate a similar change in the cells of other tissues, even in the cells of sarcoma and cancer, which are often remarkable for the large size of their nuclei and nucleoli.—*Centralblatt für der Med. Wissenschaften*, December 9, 1876.

# THE MEDICAL RECORD:

Weekly Journal of Medicine and Surgery.

M. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, April 7, 1877.

## AN ABUSE OF MEDICAL CHARITY.

We have from time to time said a good deal concerning the abuse of medical charity, but it seems that the evil is not yet. Notwithstanding the many lights in which the subject has been viewed, new texts are constantly presenting themselves. If it were not that we believe that physicians should have an opportunity of making a decent and honorable living, we could not care to preach any longer on this subject. The best task is discouraging, and particularly so in view of the readiness with which medical men themselves countenance the many measures which tend to cheapen their services to the community. At the recent dinner of the Alumni Association of the University, one of the Commissioners of Charities and Correction, in speaking of the difficulties attending the administration of his department, took occasion to say that the only class in the community who cared to do their services for nothing, who delighted to do so in fact, who begged for the opportunity, were the members of the medical profession. He could hardly understand why men whose incomes ranged all the way from \$5,000 to \$60,000 a year, were so willing to give so much of their valuable time for nothing. Of course, he could not understand that clinical advances to the physician must be had at all hazards, and in compliment to their charitable feelings as the only incentive to their efforts was almost a joke. It is intimate enough to attend hospitals without fee. The theory is, that by so doing we are not only helping the poor, but helping ourselves. Experience is against our valuable stocks in trade, and the more we add to it, the better. We do not really cheapen our services by these means, because

The poor they cannot pay,

so no one is hurt. But the trouble is that we either do not or do not limit such services to the poor, and then

the difficulty begins. This is the first step in the abuse of medical charity, of which we as a profession have taken so many, and for which we are now beginning to suffer. Our dispensaries are crowded with patients who can afford to pay, while young physicians are starving for the very crumbs of patronage. We admit that this is an old story, but it is a very true one. In spite of the code which forbids the giving away of services to any but the really needy, we are transgressing the law every day. Our eagerness to obtain clinical experience blinds us to the fact that we are carelessly throwing away pearls before swine, who will at no distant day prove the truth of the Scriptural saying.

We ask if the time has not come to consider where and when we shall stop this business. If it is a question of pure conscience with the profession in regard to the suffering poor, is it not sufficiently answered by the fact that in our dispensaries alone over three hundred thousand paupers are treated gratuitously by us every year. It is fair to assume that the number of poor treated privately equal as many more. Side by side with this, is it not relevant to consider that there is not one young physician in ten who can make a decent living? We take it that with any other class of benevolent citizens such would be considered a sufficient sacrifice to the highest Christian motives. If we view the matter in the light of a *quid pro quo* in the shape of clinical experiences, is it not time to check such mistaken professional enthusiasm?

Instead, however, of attempting to do so, we are ready to go from bad to worse, and barter our professional birthright for the smallest possible equivalent. The recent scheme of the outdoor department of the New York Hospital may serve us as an apt illustration of this point. There is in it an element of bargain and sale of the profession, which, as far as one corporation can go, fixes a very low market value for the "best attainable medical and surgical service."

We are informed that the purpose of this branch of the hospital is to give to persons of moderate means or no means at all the best attainable surgical and medical service. The charges to all who are able to pay will be as follows: First consultation, \$1, for which a ticket will be issued good for one month; for each prescription furnished, 10 cents; beds in the wards with board, \$1 a day; separate rooms with attendance, as may be agreed upon, varying from \$15 to \$50 a week.

As far as services to the really poor are concerned, this is well enough; indeed, there is no objection to the payment of a small fee by those who can afford to do no more; but where is the line to be drawn that defines the position of such as are of so-called moderate means? Certainly, any one who can pay fifty dollars a week for a room can afford to give something more than a dollar a month for medical services. As nothing is said about properly remunerating the physicians in attendance, the public have a right to assume

that the dollar per month is considered a fair professional fee for such services. We have no doubt that an institution offering such splendid inducements will be well patronized. And why not? Certainly no person who can secure medical attendance at so cheap a rate, and with such additional advantages as a large and wealthy hospital can afford, will care to patronize the struggling practitioner around the corner. It is a medical provident system, with its worst and most unjust features brought out in promising and enticing relief. Whether, however, it will work to the entire satisfaction of even the parties more directly concerned, remains to be seen. In the meantime let the young practitioner who may wish to earn small fees still continue to labor and to wait, curtail his expenses, and try to compete with this well-appointed wholesale house.

#### SANITARY INSPECTION FOR SCHOOLS.

THE State Senate Committee to whom Senator Gerard's bill for medical inspection of schools was referred, have reported the same with amendments. The latter are to the effect that instead of one Sanitary Superintendent for all the Schools, the duties of such office should be distributed to eight assistant sanitary superintendents, who shall be appointed for such purpose. This will make one inspector for each school district. These are to report monthly to the Board of Health, and copies are to be sent to the Board of Education.

The propositions are to some extent an improvement on those of the original bill, in so far as the distribution of labor is concerned; but beyond this we cannot see that much will be gained. It is well known that the Board of Education is adverse to inspection when there is a liability of its being performed by other than its own appointees. Presuming upon its prerogative, there is not much likelihood that mere recommendations as such will receive a great deal of attention. As the case now stands, all the reports from the Board of Inspectors, through the Health Board, are liable to be pigeon-holed. The supreme authority to enforce health regulations in our schools should belong to the Health Board, and not by any means rest with the school authorities. It is quite necessary that there should be no misunderstanding regarding the real responsibilities in this matter. If there is, we shall be no better off than before. While we perfectly agree that eight inspectors can do a great deal of good work, we are also certain that, to systematize the same and make it really effective, some one of the number should be in the relation of sanitary superintendent to the rest. Thinking this point is worthy of the consideration of our legislators, we offer it accordingly.

**SULPHO-CARBOLATE OF SODA IN SCARLET FEVER.**—A subscriber asks for some information concerning the value of sulpho-carbolate of soda in scarlet fever.

## Reports of Societies.

### NEW YORK PATHOLOGICAL SOCIETY

*Stated Meeting, March 14, 1877.*

DR. E. G. JANEWAY, PRESIDENT, IN THE CHAIR.

#### SPONTANEOUS EXPULSION OF A LARGE INTRA-UTERINE FIBROUS TUMOR.

DR. R. OSGOOD MASON presented a tumor of uterus which had been spontaneously expelled by patient, with the following history:—

The patient, Miss B., at 43 years, American birth, and a teacher by occupation, was a tall, well formed woman, naturally of good health and good energy. For twelve years she has had profuse menstruation, and latterly she would have scarcely a week in month without flow, and most of the time it was excessive. Abdominal enlargement did not attract attention until six years ago, since which time it came conspicuous, and for the last three years she disliked to be seen in the street, her appearance being that of a woman well-advanced in pregnancy. The chief symptoms were nausea, sleeplessness, hemorrhage and increase in size. She also had more or less paludic anemia was excessive, and her bowels never moved without injection.

She had never been examined until three months ago, when she was told that she might possibly have a small tumor, but that her abdominal enlargement was mostly the result of an enormously enlarged liver extending downwards.

Subsequently, in consultation with an eminent gynecologist of this city, she learned the true nature of her disease, but received little encouragement regarding ever being rid of it, the attending physician being advised that all he could do was to control the hemorrhage.

She came under my observation February 6th, about five weeks ago, when I obtained the above history, and also learned that she had been taking pretty large doses of ergot for two or three weeks without apparent benefit, and that now it had become so disgusting to her that she was unable to retain it.

Her appearance was most wretched, and her condition on account of hemorrhage was such that she refused an examination, saying she would send for soon.

A few days later, February 13th, I saw her at home, when she showed me some membranous substance which she said she had been passing for two or three days, and also some distinct fragments of a fibrous tumor.

An examination now revealed a condition of the uterus very similar to that of commencing labor. An enormously enlarged uterus extended above the umbilicus, the fundus of the womb was low down and soft, and the os dilated so that the finger passed through without difficulty; but within the uterus, instead of a foetal head, it encountered fragments of the tumor, easily movable, but for the most part strongly attached to the main mass. Some small pieces, however, became detached, and came away in my hand.

The patient was informed of the state of affairs, encouraged to hope she would be rid of her tumor in a week or two without any serious operation. She also told that it could be removed at any time by operation, if it became necessary.

After this fragments of considerable size were detached, mostly by twisting them around and around

with the finger, and removed. Forceps were of little use; one blade of a pair of placenta forceps passed to the uterus, and used after the manner of a curette, rendered the most assistance. After each operation the uterus was washed out with a weak lotion of Barraque's solution.

On the eighth and ninth days from my first visit two large pieces, constituting the main bulk of the mor, were removed, and on the 5th of March, twenty days from my first examination, the last fragment came away.

During all this time there had been no uterine contractions of any account, but only occasional spells of severe backache.

The hemorrhage ceased as soon as enough of the mor had come away, so that the uterus began to be reduced in size about the fourth day of my visits.

The patient had no distinct chill, but a *chilliness*, followed by moderate fever and sweating, on the evening before the first large portion came away.

The temperature never went above 101 degrees, and pulse never above 112.

Within twenty-four hours after these large fragments were removed both pulse and temperature came normal, the appetite became good, and sleep refreshing; general improvement immediately took place, and continued even while the last portions of the tumor were being discharged.

An inoffensive purulent discharge continued for some days longer.

Yesterday, March 14th, I found the patient looking better than before her illness. She had been sitting as usual for the three previous days, was employed sewing, and was looking forward to resuming her usual occupation in a few days. The uterus at this time measured a trifle over three inches. The weight of that portion of the tumor which was preserved and substitutes the specimen here presented is fourteen ounces, and I should judge that at least one-fourth of the whole was lost.

DR. MARY P. JACOBI referred to a somewhat similar case, the specimen from which had been sent to her in Boston. Portions of the growth had been successively removed during a period of four months, the patient ultimately dying of myosarcoma.

DR. JANEWAY saw a patient some years ago with a similar tumor as the result of hemorrhage, due to laceration of the pedicle during the time it was being discharged.

DR. M. P. JACOBI presented a specimen for a candidate, accompanied with a written history.

#### CASE OF ULCERATIVE ENDOCARDITIS POSSIBLY OCCASIONED BY MIASMATIC POISONING.

DR. BEVERLEY ROBINSON presented a case of ulcerative endocarditis with the following history:

A. D., aged fifty years, was admitted to the penitentiary hospital on Blackwell's Island, March 5, 1877.

The patient has suffered from intermittent attacks of chills and fever during the past week, and also from moderate and persistent pain in the left side of the chest, irradiating towards the left shoulder. Yesterday, March 4th, he had another severe chill. This was followed by fever, abundant perspiration, and subsequently he felt much better. To-day, March 5th, at mid-day, patient again complains of chilliness, though his skin is hot to the touch, and the thermometer marks 106° Fab. in his axilla.

Upon examination of the cutaneous surface and of the eyes a slight yellow tinge is noted. Liver somewhat sensitive to percussion, but its area of dulness is not augmented. Dulness in region of spleen has

somewhat increased. Pulse is tolerably full, strong, and frequent. The number of beats was not recorded. About every ten to twenty pulsations there was a short intermittence. The heart was found to be hypertrophied, and a loud, systolic, blowing murmur was heard, with its maximum of intensity at the apex, and conveyed into the sub-axillary region on the left side. The patient has had occasional attacks of cough; the respirations were rapid, and physical examination of the lungs revealed the signs of emphysema and generalized bronchitis. At 5 P.M. patient commenced to have hicough, which continued until 4 A.M. on March 6th. At 6.30 A.M. of this day patient was quiet, complained but little, and ate a small meal. At 9 A.M. he was in a state of stupor, the pupils were contracted equally, and the pulse was very feeble. Upon the administration of stimulants (whiskey by the mouth and ether by hypodermic injection) patient recovered himself sufficiently to answer a few questions intelligibly. There were at that time no signs of localized or general paralysis. In a brief period of time patient again relapsed in a state of stupor, and finally became wholly comatose, and remained in this condition until death, which occurred at 1.30 A.M. on March 7th. During the last few hours of life the urine was drawn off with a catheter. It contained a small quantity of albumen, with casts of undetermined nature. Temperature shortly before death was 104.5 Fah., in the axilla.

*Autopsy* was made by Dr. E. A. Maxwell, one of the curators of Charity Hospital, twenty-eight hours after death. *Body* large and well developed; marks of nine cups over left side of chest. There is a small bruise on inner side of left patella. Rigor mortis well marked. *Head*: Bones, sinuses, and dura mater normal; vessels at base normal. Pia mater and brain substance moderately congested. *Thorax*: heart weight twenty four ounces; pericardium normal. By hydrostatic test, large aortic regurgitation; mitral valves sufficient; right ventricular walls twice their normal thickness, firm; cavity small; right auricle dilated; left ventricular walls markedly hypertrophied; cavity slightly increased; left auricle slightly hypertrophied; cavity normal. *VALVES: aortic*: posterior and right leaflets are partially destroyed, the loss of substance extending in a semicircular direction from the corpus Aurantii of right leaflet to the same point posteriorly, the greatest loss of substance being at the point of attachment of these two leaflets. Attached to the right leaflet is a shred one inch and a half long, a portion of the free border of the valves. The base presents a ragged appearance, is roughened by calcareous spiculae, and has attached to this surface crumbling masses of fibrin. The remaining portion of the leaflet (posteriorly) shows a calcareous plate in its centre, the free end of which projects into the ulcerated border. *Mitral*: slight amount of thickening of free borders. *Aorta*: shows chronic endarteritis. *Lungs*: no adhesions, markedly emphysematous, congested and oedematous, evidences of bronchitis. *Abdomen*: liver normal; spleen enlarged; parenchyma diffused and contains a small, wedge-shaped infarction. *Kidneys*: each contains numerous hemorrhagic infarctions of varying size from a mere point to one-quarter of an inch at base, mainly throughout the cortical portion; a few extending from the pyramids mainly in the yellow stage. *Uvula*: dilated, moderate amount of pyelitis. *Bladder*: normal. *Stomach*: shows post-mortem digestion and contains some bloody fluid. *Intestines*: small, and contain throughout numerous small, hemorrhagic infarcti.

*Remarks*.—Since Senhouse Kirkes first brought to

the attention of the profession a peculiar form of diseased endocardium, characterized especially by an ulcerative process affecting the valves, observers in cardiac affections have viewed this malady with much interest. And this feeling is readily explained in part by the relative infrequency of this kind of heart lesion, in part by the obscurity relating to the primary or specific cause which presides at its formation. For these two reasons, also, the correct diagnosis prior to death has not usually been made, and the revelations in the post-mortem room have been a surprise. No doubt Virchow, in his *Cellular Pathology*, unravelled many intricate points in ulcerative disease of the endocardium, which to the time of his researches in this direction had been imperfectly investigated, and later writers have cleared up certain additional questions of nature and etiology. Still, however, the *finis et origo* of the disease is debatable. Is it a disease of inflammatory type, as the name ordinarily given to it would seem to imply? Is it a local manifestation of a systemic blood dyscrasia of acute infectious nature, as the general phenomena afford strong testimony? Against the former belief the condition of adynamia rapidly produced, and irrespective of pre-existing symptoms of such morbid development, together with the wholly negative signs made known by autopsies, militate forcibly. In favor of the second view we have the analogies which have been noted, viz.: the insidious commencement, the repeated attacks of chilliness, the sudden prostration of the forces, the extreme gravity of its course, the transport of septic material in many organs, the local and general phenomena resulting from this migration, the almost certain and very speedy fatal termination.

The puerperal state appears conducive to this disease, and after a like manner, perhaps, pyæmic poisoning and certain badly defined septic influences. I cannot accept any relationship between rheumatic arthritis and ulcerative endocarditis, even though this opinion has been advocated by high authorities. The great similarity of the local changes in this disease to those which take place in diphtheria has originated the term which is now in common use with many German physicians, of "diphtheritic endocarditis." And further Lancereaux has endeavored to trace this affection, in one of its varieties at least, to the poison of miasmatic fever. To this class the case I here report may possibly be attached, if the fact that the ulcerative process was *exclusively* limited to the aortic valves be considered of significance.\*

DR. M. P. JACOBI asked if there was any of this so-called ulcerative endocarditis associated with the presence of micrococci.

DR. ROBINSON did not believe that micrococci had any more significance in causing this condition of things, than in many other pathological conditions with which they were found to be associated.

DR. JANEWAY thought that the lesions of the valve were of ancient origin, as shown by the presence of calcification, and that the ulcerative process was the result of it, following a recent localized inflammation.

DR. HEITZMANN concurred in this view.

DR. M. P. JACOBI asked if the brain had been examined, and if so, whether any emboli were discovered in that organ.

DR. ROBINSON stated that the brain had been examined, but that nothing abnormal had been discovered.

DR. JANEWAY referred to the possibility of finding microscopic emboli in such a case, a condition found upon the observations of Bastian.

DR. ROBINSON wished to ask what influence malaria had in causing disease of the heart.

DR. JANEWAY did not believe that there was a such influence. He thought that the exacerbation in Dr. Robinson's case could be explained by the occurrence of embolic deposits in different parts of the circulation.

#### RARE FORM OF FRACTURE OF LOWER PORTION OF LEG

DR. ERSKINE MASON presented a rare form of fracture of the tibia removed by amputation from a young man, 21 years of age, who entered Roosevelt Hospital on June 1, 1876. The history the patient gave of himself was, that six weeks before admission he had been thrown from his wagon, falling upon a pile of stones and sustaining a fracture of both bones of the leg. The limb was put up in splints by some practitioner, who bandaged it so tightly that a slough formed on the inside of the foot, below the malleolus and general mortification of the leg was threatened. When admitted, the foot was in a state of extreme tension, and, together with the leg, was very much swollen. A probe passed through the opening on the inside of foot detected dead bone. Several sinuses formed subsequently upon the dorsum of the foot at the lower portion of the leg, and dead bone was also detected in the region of the os calcis.

On Jan. 10th, Dr. Sands, who was then on duty, had the patient etherized, in order to excise the dead bone and if possible place the limb in a more favorable position. At the consultation held on the case there was a difference of opinion as to the precise nature of the injury, some believing it to be a fracture of the lower portion of the tibia, displaced forwards, and others an anterior dislocation of the astragalus.

The patient did remarkably well for three weeks after the operation, when more sinuses appeared on the dorsum of the foot leading to bare bone. This condition was attended with extreme pain, and a general breaking down of strength. Finally the limb was removed by Dr. Mason, Feb. 24th.

The specimen showed a fracture of the fibula just above the malleoli, union having taken place in a very faulty position. The line of fracture of the tibia was an inch and a half above the ankle-joint, extending through the articular surfaces. The lower fragment of the tibia had become displaced forwards, forming a marked and curious projection, and had united that position with the anterior portion of the lower end of the upper fragment. The astragalus was partially thrown from its bed. The lower fragment of the tibia first became the seat of necrosis, and the disease extended itself so as to involve nearly all the tarsal bones.

DR. MASON remarked that he had met with two similar cases of fracture, but in both instances they were recognized, and were placed in position at once.

DR. HEITZMANN being called upon, made a report to the effect that the tumor of the thyroid gland, presented at a previous meeting by Dr. Ripley, was the seat of medullary cancer.

(To be continued.)

\* In the *Archives Gén. de Méd.*, p. 673, 1873, Lancereaux writes as follows: "There exists by the side of puerperal endocarditis, a form of ulcerative and vegetative endocarditis preferably localized upon the semi-lunar valves of the aorta, common amongst individuals affected with intermittent fever."

METRIC SYSTEM.—The Union Medical Association of North-Eastern Ohio, at the recent quarterly meeting recommended to its members the adoption of the metric system in writing prescriptions.

## Correspondence.

## THE SAFETY OF THE NASO-PHARYNGEAL DOUCHE.

TO THE EDITOR OF THE MEDICAL RECORD.

EAR SIR:—An article in No. 333 of your valuable journal, entitled "The Danger Attending the Introduction of Fluids into the Nasal Passages," by Dr. Albert H. Buck, would, I fear, if unanswered, prevent any a surgeon and physician from using a most valuable and (with care) *safe remedy*, for one of the most troublesome and obstinate diseases of this climate, *viz.*, naso-pharyngeal catarrh.

Dr. Buck in his paper relates ten (10) cases of inflammation of the middle ear caused by the introduction of fluids into the nasal passages. As a proof that such is the fact the doctor mentions that pain was felt in the ear or ears, on an effort being made to "*blow the nose*" shortly after the introduction of the fluid. In carefully looking over these cases, I see no evidence, except in cases 3 (where *cold* salt and water was snuff-up into the nose) and 5, that the use of the fluids and accompanying inflammations of the ear were anything more than coincidents. Every physician who has paid any attention to the study of diseases of the ear is well aware that one of the earliest symptoms of middle ear catarrh and purulent inflammation of the middle ear perceived by the patient is pain when he "*blows his nose*," and also that naso-pharyngeal catarrh is one of its most frequent causes.

During the past eleven years' experience in treating naso-pharyngeal catarrh, I have been in the habit, previous to applying medicated vapors, atomized fluids, more direct applications to inflamed or ulcerated surfaces, of washing out the nares and pharynx by means of the nasal douche, posterior nares syringe, having the patient snuff up a warm solution of chlorate of potash, or some fluid to cleanse the nares. And in no instance have I seen purulent inflammation of the middle ear caused thereby. On the contrary, I think I have seen cases of purulent inflammation of the middle ear and perforation of the membrana tympani that might have been prevented had this method have been adopted, as the following cases will tend to show:

In 1872 I was called to see a little girl about five years of age, suffering from naso-pharyngeal catarrh, that caused a constant and annoying cough, especially at night. Internal remedies failing to relieve it, I frequently washed out the pharynx and nose with a warm solution of salt and water, and soon taught the child to use the nasal douche herself, *viz.*, with the assistance of her mother or nurse. The douche invariably gave her relief. This little patient has continued to use the douche (whenever suffering from a fresh attack of catarrh) ever since, and always finds immediate relief, and has never had any trouble with her ears. A sister had a slight catarrhal trouble, so slight indeed, that my attention was first called to it by its extension into the middle ear and perforation of the drum. Two younger sisters while infants both suffered from nasal catarrh, but owing to their age and restlessness I was unable to use the nasal douche with a syringe. Yet in both the inflammation extended into the middle ear, and the drums were perforated. In the case of one I was obliged to make an incision over the mastoid portion of the temporal bone

to liberate pus. Had I been able to have kept the nasal passages clear by warm salt and water or other means, I think their chances of suffering from purulent inflammation of the middle ear would have been very much less. To show my belief in the efficacy of the nasal douche I shall mention only one other case, and that of my only son, thirteen years of age, who one year ago suffered from a naso-pharyngeal catarrh that affected the Eustachian tubes, causing deafness, destroying the sense of smell, and altering the voice. Repeated applications of warm salt and water by means of nasal douche and Politzer's bag used soon after gave almost entire relief. The relief was so great and well remembered that now, whenever he has a cold in his head, he invariably desires to use the douche.

The object of this letter is not only to place on record an objection to the prevailing tendency to condemn a useful method of treatment, but to invite further investigation of its real merits.

Yours respectfully,

HOWARD PINKNEY, M.D.

24 E. FORTY-FIRST ST., N. Y.

## "PHOSPHORUS ASSIMILATION."

THE ELEMENT AND ITS COMPOUNDS CONSIDERED AS TO AVAILABILITY."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In your issue of January 27th. an article appeared with the above caption, written by Dr. R. W. Gardner, of Jersey City.

I cannot agree with Dr. Gardner in many of his assertions, or in the conclusion he has drawn from them. His first sentence may be deemed almost an axiom: "When phosphorus is administered in a free state its irritant action forms the greatest objection to its use;"—but the conclusion he arrives at, that it must be given with food, "otherwise it is found to attack the mucous surfaces," is not in accordance with numerous experiments I have performed. These hematoma, or, as they are frequently called, ecchymosed spots, are not found upon the mucous membrane of the stomach from the local action of phosphorus, for the same spots are found upon the serous membranes and sometimes upon the external skin. They are produced by the general action of the phosphorus upon the system, and are not found until the patient is under the toxic influence of the drug; then they are found upon the heart, the pleura, the peritoneum, quite as often as upon the mucous surface of the stomach, and are owing to the primary action upon the kidneys causing acute Bright's disease and subsequent fatty disintegration of other structures. I have seen these spots at the very commencement of their formation in the living animal. From the poisonous action of free phosphorus upon the blood, the blood-discs break down, and in certain spots in the capillaries these broken discs adhere to the walls of the vessels and form a nucleus for the adhesion of many others; the vessels at these spots become softened, oily, disintegrated, and a larger or smaller hematoma is found. If this plastic exudation is examined with the microscope it is found to consist of minute oil-globules and broken blood-discs. Experimental therapeutics has revealed these actions to me in the animal while living, and they may be seen in any animal poisoned with phosphorus in all parts of the body after it is dead. I have studied the action of free phosphorus so closely that I can at will cause the death and production of

these spots on any number of animals on any given days I may wish. If Dr. Gardner will examine the Transactions of the Am. Med. Association, vol. xxiii., pp. 644 to 652, he will find many cases there recorded; also the Trans. N. Y. State Med. Society of 1876, pp. 100 to 125.

In the next paragraph Dr. Gardner has fallen into the same error with Thompson, Turner, Squibb, and a host of other writers. "It has such a powerful affinity for oxygen," "this explains its corrosive action on the stomach."

As soon as phosphorus unites with oxygen it loses its poisonous properties, even if this union is its lowest oxide. Phosphorus is nearly always administered in some oleaginous material for the purpose of preventing its oxidation, and it does prevent it most effectually, and we find the effect of the free uncombined phosphorus in the derangement of the digestive organs, and have proof of its presence in its unity by the phosphorus eructations, and when an animal dies from its action by the phosphorus smell of the whole body. According to Thompson's theory,  $\frac{1}{10}$  of a grain of phosphorus dissolved in oil and given diluted with some other substance, instead of spreading over the surface of the stomach and becoming absorbed, falls upon one little spot of the stomach and an immediate conflagration takes place, by its union with oxygen, and burns up the membrane.

Again, Dr. Gardner says: "Phosphorus cannot be absorbed in its pure state; a certain degree of oxidation must have taken place before it reaches a condition adapted for assimilation." Why can it not be absorbed? It is in a state of solution! Its congener arsenic is readily absorbed! It has many times been found after absorption in a free state. If it becomes oxidized it loses its characteristics, as sulphur does in its union with oxygen.

In the next paragraph Dr. Gardner evidently does not mean, though he infers, that the remedial action of the oxides of phosphorus are produced by taking free phosphorus and having it become oxidized in the system. This action very seldom takes place, and I am certain that one so skilful would never administer free phosphorus when he wished to produce the effects of the lower oxide—the hypophosphite—"in contributing to nerve power and vital force."

Free phosphorus is one of the most dangerous medicines we possess, even in the hands of one well skilled in its use, and in my opinion should never be administered to man until one has fairly and fully learned its effects and toxic influences by numerous experiments upon the lower animals.

Lehman has demonstrated that a man in good health excretes in his urine 54 grains of the phosphates daily. Dr. Gardner certainly would not expect to "contribute to nerve power and vital force" by restoring this loss in giving free phosphorus "in  $\frac{1}{10}$  grain doses."

The balance of Dr. Gardner's article has been closely studied, and is worth a careful perusal, but many of the points he has given need a more lengthened explanation. Thus: "Phosphorus exists in the vegetable world in the condition of *phosphate* only." This would be better understood had he said that "by the ordinary method of analysis it is only found in vegetables in the state of a phosphate; but, by later and more improved methods of analysis, hypophosphites have been found in vegetable as well as animal tissues. I would refer to Craze Calvert's investigations, and to my "Essay on Phosphorus," Trans. Am. Med. Ass., vol. xxiii.

To Churchill is due the credit, some eighteen years ago, of introducing the hypophosphites, or the lowest

oxide of phosphorus, to the attention of the profession and he has demonstrated by ample testimony the great utility in debility and consumption. To enlarge upon Churchill's views, I for years labored to produce more easily assimilated hypophosphites than those made in the laboratory; and through my Essay of 1872, the profession demanded from me these improved hypophosphites until I was compelled to put them into other hands. Through the recommendation of the profession only, Messrs. Caswell & Hazard supplied from 2,000 to 3,000 bottles of "Vitalized Hypophosphites" monthly.

Dr. Gardner is correct when he says that all *phosphoid* (I coin this word) preparations in the system gradually become converted into its highest oxide—the phosphate; in which condition it loses its utility as a nutrient, is eliminated from the system, and may again go through organization or "vitalizing" plant life before it becomes in a condition to nourish and support animals.

I think Dr. Gardner is again in error when he says that the hypophosphite salts should be converted into solution and kept in the form of syrups. My experience has proved to me that they keep unchanged a longer time (in fact, an indefinite time) when kept in the "vitalized hypophosphites" are—in the form of a dry powder; even the oleaginous ones are kept maintained unaltered. I have found those preparations *in syrup* to be constantly and increasingly formed into phosphates, and some that have been kept but very short time, and were perfectly pure hypophosphites when made, were *wholly* converted into phosphates within a month.

Dr. Gardner will excuse me if I have criticised *minor points*. I am happy to see his able paper, and I know that he will argue only for truth's sake. I have studied the subject of phosphorus deeply, and feel interested in all intelligent writing upon it.

Within a short time I have presented to the profession, through Messrs. Caswell & Hazard, a peculiar protagon or phosphoid—nitrogenous element as exists in the germinal portion of wheat, and the brains of animals and fishes. It has the following

#### COMPOSITION IN 100 PARTS.

The Phosphoid-Nitrogenous element, isolated,	$C_{12} H_{79} N_6 P_8 O_{12}$	.....	10	pa
" Hypophosphite of Sodium, $Na_3 P O_2$			2	"
" " " Calcium, $Ca_3 P O_2$			2	"
" " " Potassium, $K_3 P O_2$			2	"
" Animal and Vegetable Albumen			5	"
" Phos-glyceric Acid, $C_3 H_5 P_2 O_2$			5	"
Free Hypophosphorous Acid, its solvent, $H_2 P O_2$			5	"

Respectfully yours,

SAMUEL R. PERCY, M.D.

47 W. THIRTY-EIGHTH STREET.

#### ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from March 25 to March 31, 1877.*

DE GRAW, C. S., Ass't Surgeon. To report to the Commanding Officer, Dept. of the South, for assignment to duty. S. O. 63, A. G. O., March 24, 1877.

JESSOP, S. S., Ass't Surgeon. To report to the Commanding Officer, Dept. of the South, for assignment to duty. S. O. 63, C. S., A. G. O.

MOFFATT, P., Ass't Surgeon. To report in person at the expiration of his present leave of absence, to the Commanding General, Division of the Atlantic, assignment to duty. S. O. 63, C. S., A. G. O.

WEN, C., Ass't Surgeon. Assigned to duty at Mad-Barracks (Sackett's Harbor), N. Y. S. O. 70, Division of the Atlantic, March 28, 1877.

ORTER, J. Y., Ass't Surgeon. Granted leave of absence for twenty days. S. O. 61, Dept. of the South, March 29, 1877.

HUFELDT, R. W., Ass't Surgeon. Relieved from duty at Indianapolis, to proceed to Fort McHenry, to complete his unfinished business, and then comply with orders assigning him to duty in Dept. of the South. S. O. 68, Division of the Atlantic, March 26, 1877.

ERLEY, H. O., Ass't Surgeon. Relieved from duty at Jeffersonville, Ind., and to comply with orders assigning him to duty in the Dept. of Dakota. S. O. 69, Division of the Atlantic.

Medical Items and News.

CONTAGIOUS DISEASES.—Comparative statement of cases of Contagious Disease reported to the Sanitary Bureau, Health Department, for the two weeks ending March 31, 1877.

PROVIDENT DISPENSARY SYSTEM.—At the next meeting of the Public Health Association of New York, which will be held in the rooms of the Academy of Medicine, No. 12 West Thirty-first street, on Wednesday evening, April 12th, at eight o'clock, Mr. James C. Bayles will present the report of the special committee appointed to consider the practicality of producing the *Provident Dispensary System into this city*. The profession are invited to attend.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.—At a stated meeting of the Medical Society of the County of New York, held March 26th, 1877, it was resolved to grant certificates of membership to the following named gentlemen: Drs. L. R. Walton, Robert Curtis, P. A. Callan, R. H. Saunders, W. C. W. Glazier, R. McGregor, K. Van Arsdale, M. D. Dubois, E. D. Meeler, G. M. Lefferts, S. D. Terry, A. V. Brailly, D. Buck, W. J. Purcell, E. Gruening, K. Reid, L. Herber, J. T. Darby, E. T. Ely, M. E. Tully, C. Wilson, C. Dixon Varly, E. B. Bronson, David Matthews, J. Milhau, Wm. W. Jones, J. W. Warner, J. W. Smith, J. F. Kennedy, R. O. Mason, L. Damainville, E. Hyde, G. M. Bull, J. M. Hills, L. H. Sayre, S. Sherman, H. G. Forbes, and J. J. Reid.

THE LATE DR. HERMANN ALTHOF.—The members of the surgical staff of the New York Eye and Ear Infirmary have heard with profound sorrow of the death of their long-time associate and friend, Dr. Hermann Althof, and desire to express to the family their deep sympathy with them in their great loss, and show their own appreciation of the character of their deceased friend.

Dr. Hermann Althof we, his associates, had an enthusiastic coworker, a long-tried and able adviser, an earnest, conscientious executive chief, and, better than a devoted, warm-hearted friend. Few of us have

not had occasion to apply to him for advice and assistance, and none has ever found him wanting. The combined beauty of his character as man, physician, and friend was but seldom met with. To a rare skill in diagnosis was united a wonderful manual dexterity, and a judgment that so seldom proved faulty, as to seem almost unerring. We may well mourn the loss of a man stricken down in the prime of life, singularly fitted for his duties, profound in his knowledge, and skilful in his art, whose wise counsel and genial nature endeared him especially to us. By this sudden blow the Infirmary has been deprived of one whose skill and learning as a surgeon, whose integrity and loyalty as a man, and whose zeal and experience in the best interests of the institution, it could ill spare. As executive surgeon we have lost one who, sound in judgment and efficient in action, was tireless in his efforts for the good of the Infirmary. His death is a real, irreparable loss. His place now empty can never be filled; but his tender, loving spirit, his earnest life will preserve his memory ever fresh and green in our hearts. His whole life furnishes a rare example for all to follow, and as the best tribute which we can pay to his worth we can but attempt to uphold by our own endeavors the lofty standard of excellence he himself professed.

(Signed)

HENRY D. NOYES,  
RICHARD H. DERBY,  
CHARLES S. BULL, } Committee.

OUT-DOOR DEPARTMENT OF THE NEW YORK HOSPITAL.—The following gentlemen constitute the attending staff: Surgery, Drs. S. F. Morris and G. F. Blauvelt; Heart and Lung Diseases, Drs. Beverly Robinson and G. G. Wheelock; Diseases of the Head and Abdomen, Drs. T. A. McBride and A. McL. Hamilton. From 3 to 4 P.M.: Skin and Venereal Diseases, Drs. L. D. Bulkley and R. Abbe; Children, Drs. F. P. Kimball and H. F. Heineman; Women, Drs. G. S. Winston and F. P. Foster.

REMEDY FOR NERVOUS HEADACHE.—Dr. John E. Lockbridge, of Indianapolis (*American Practitioner*), gives a remedy for headache. He says: "Having observed that bromide of potassium, in twenty or thirty grain doses, and tincture of aconite root, separately, relieved more cases than any remedies I had previously exhibited, I experimented with large doses of the drugs combined. For several years I have been in the habit of giving in these cases sixty grains of the bromide of potassium and ten drops of the tincture of aconite root in a wineglassful of water, the same to be repeated in an hour or two if the head be not relieved; but a repetition of the dose is very seldom required. In the case of ladies and others who wish to have a remedy always at hand, or who are about to start on a journey, I supply them with the following mixture:

℞. Bromide of potassium..... ʒ ij.  
Tincture of aconite root..... ʒ i.  
Distilled water, q. s. .... āā ʒ ij.  
Simple syrup, q. s. .... āā ʒ ij.

℞. S.—Take a desertspoonful in some water every hour until relieved.

My recipe may smack of empiricism in appearing as a panacea for every variety of headache, let the cause be what it may and the accompanying symptoms be what they will; but I am willing for it to rest under the soft impeachment, if indeed it relieves promptly only a moiety of these distressing cases. I will not now attempt to give the *rationalis* of this seeming paradox, or the *modus operandi* of the cure, but will simply remind my readers that this nervous headache is a para-

doxical, capricious, discouraging, and worrying affection."

ON A NEW TREATMENT IN POST-PARTUM HEMORRHAGE, BY W. HANDSEL GRIFFITHS, M.D., L.R.C.P.E.—Although not an obstetric practitioner, I have recently been consulted in two cases of severe *post-partum* hemorrhage. In both cases every means had been adopted, but unavailingly. It flashed across my mind in the first case to try the effect of the ether-spray, and accordingly I directed a large spray over the abdominal walls, along the spine, and over the genitals; the uterus at once responded, and the cessation of the hemorrhage was almost immediate. In the second case I lost no time in adopting a similar treatment, and with an equally successful result. I have consulted several eminent obstetric practitioners in Dublin, and am informed by them that they are not aware that this treatment has been heretofore proposed. The advantages of the ether-spray over the application of cold water and the other means usually adopted in these cases must be patent to every practitioner of midwifery.—*London Practitioner*.

NEW MEDICAL COLLEGES.—It is rumored that there will be a medical college in Toledo, Ohio; of course this will soon be followed by another. One brand new medical college has just been organized in Nashville. Rumor speaks of one to be projected in New Albany. Fort Wayne has just undergone the throes of parturition; so there is an infant school there. The air is thick with rumors of other medical gentlemen being ready "to supply a want" by opening medical colleges elsewhere. It is said that if physicians would only charge each other's families for services rendered, this act would check the new college mania. At present, men find it economical to study medicine to enjoy freedom from physicians' bills. If any one desires to cease paying doctors' bills, he has only to become a doctor. The best counter-movement is for every physician to charge every physician's family for medical services given!! If this is not done, there will soon come a social condition, when, if it cannot be said that "every man's his own doctor," it can at least be declared that every man is his neighbor's doctor. Indeed, it seems that the great millennium is near at hand; all are to be doctors, and therefore all are to be good and perfect men!—*American Bi-Weekly*.

FACULTY PRIZE EXAMINATION OF COLLEGE OF PHYSICIANS AND SURGEONS, N. Y.—The following was the schedule for the Faculty Prize Examination of the class of 1877, ten of those passing the best general examination for graduation being allowed to compete:

Time allowed, three hours; 7½ to 10½ P.M. Answers to all the questions below are desired. If in any one of the seven branches all the questions are left unanswered, the paper in which such omissions occur will not be submitted to the Committee of Award. Write your name on each sheet, write answers only on one side of the sheet, and page the sheets as you go along.

*Anatomy*.—1. Give the origin, course, and distribution of the External Carotid Artery and its branches. 2. What muscles are supplied with nerves from the Cervical Plexus?

*Physiology*.—1. What is the mechanism by which the air is inspired and expired in respiration? 2. Which of the Cranial Nerves are motor, which are sensitive, and which are nerves of special sense?

*Chemistry*.—1. Where does Oxygen occur in nature? How is it obtained? What are its properties? What its functions? 2. Name the common impurities found

in drinking water, and give their origin and influence on the health of persons using it. 3. What is a hydrocarbon? 4. What is a carbohydrate? 5. What is a fat?

*Materia Medica and Therapeutics*.—1. Give a simple formula for adapting cow's milk for use as food for an infant three months old. State the means by which the tendency of the casein of the cow's milk to coagulate in large lumps can be counteracted. 2. Name the alcoholic beverages which are especially to be forbidden to persons with a gouty tendency. 3. State briefly the clinical effects which are peculiar to poisoning by Physostigma as contrasted with poisoning by Conium. Name the best pharmaceutical preparation of Conium. 4. What is Ergot? 5. What is Elarium?

*Pathology and Practical Medicine*.—1. Give the different Heart-Murmurs; their situation, mechanism and significance. 2. Cirrhosis of the Liver—its lesions and the secondary lesions due to it, its symptoms, and the cause of these symptoms. 3. Give the method of treating and managing a case of simple acute Testiculitis.

*Surgery*.—1. Describe the microscopic anatomy of granulation tissue. 2. With what injury is Dislocation backward of the Radius and Ulna most liable to be confounded? Give the differential diagnosis. Contrast the local treatment of Abscess and Diffuse Suppuration, both acute. 4. What are the indications for the exceptionally early opening of collection of pus?

*Obstetrics and Diseases of Women and Children*.—1. What measures should be adopted, in cases of Breech Presentation, when the breech refuses to descend, and becomes impacted in the pelvic cavity, either from uterine inertia or disproportion between the breech and the pelvis? 2. What is the mechanism of the pulsion of the Placenta when left to Nature? 3. What constitute the inclined planes of the Pelvis, and what is their direction? 4. What is the composition of blood in Pregnancy? 5. What is the pathology of Flexions of the Uterus? 6. State on what day of disease the eruption appears in Varicella—Variola—Measles—and Scarlet Fever; and on what part of the body it is usually first seen.

THE ANATOMIST.—We have received from R. J. Rendsohn, a publisher of this city, an exceedingly well-executed etching (7 × 10 inches) from the original painting by Prof. Max upon the above subject. The painting was exhibited at the Centennial Exhibition, and no doubt commanded considerable attention. The engraving represents an anatomist while drawing the cloth from a female "subject" whom he is supposed to recognize as one of his relatives. The idea is an extremely sentimental one, although the professor, seated beside the table in an easy and graceful position, contemplates the situation with calmness which would probably be unbecoming in any one but an anatomist. It is intended for an office picture, and will doubtless serve a useful purpose as such.

EXPERT TESTIMONY.—The *Lancet* very properly objects to the prevalent methods of expert testimony, maintaining that when a medical man allows himself to be "retained" in a case, he subordinates science to the exigencies of personal interest.

MAINE PHARMACY LAW.—A pharmacy law, similar in its provisions to our own, has been recently passed in Maine, receiving the signature of the Governor February 9th.

## Original Communications.

## ON THE UNITY OR DUALITY (?) OF SYPHILIS.

By J. L. MILTON,

SENIOR SURGEON TO ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN,  
LONDON, ENGLAND.

## PART II.

ON the 6th day of December, 1874, I was requested by a physician to give an opinion on the case of Mr. ——. I found him suffering under a most copious eruption of papules, numbers of which were tubercular. His face was in such a state that he could not be induced to leave the house during daylight, and he allowed no one to see him except one or two immediate relatives and his medical attendant. In addition to this, the tubercles were spread in clusters over the upper part of the back, the shoulders, chest, arms, and forearms; some being covered with scales, others partially suppurating, and a third set surmounted with crusts. On the left side of the anterior arch of the palate was a superficial erosion covered with yellow secretion, and on the inside of the lower lip, about the centre, was a similar patch, ragged in shape and extremely painful. The patient complained much of rheumatoid pains in the chest, shooting through to the back.

According to his account, which was carefully compared with his narrative at a later visit, the suspicious connection took place early in May, but no result ensued for nearly or quite five weeks after; on this point the patient's statements were most explicit. The first thing noticed was a "tender spot" on the central line of the dorsum of the penis, just posterior to the glans, which in this patient was entirely covered by the foreskin. This gradually spread till it was as large as a sixpence. It slowly became covered with a crust, under which formed "a good deal of matter." There was no hardness whatever, either at the edges or base. On this point, also, the patient's answers were most distinct; and as he was a highly intelligent man, judicious and fond of inquiring into such matters, of mature judgment, being quite thirty years old, and as he had repeatedly tried to ascertain whether there was any induration, his medical attendant having mentioned this point and confirming his statement, I think his account might be accepted. On examining the seat of this sore I found neither the least vestige of hardening, nor any marks showing such loss of tissue as we might expect to see after recent perforating soft sore. Enlargement of the glands in the left groin followed the appearance of the chancre, and could still be felt. The chancre closed in about five weeks from its being discovered, roseola showing itself about the same time; the middle of July, as nearly as the patient could estimate, and two months and a half or so later, the tubercles began to appear.

It seemed desirable to set forth these points a little in detail, so as to give the reader, at the earliest possible opportunity, the key-note to the objection now to be raised against some of the views upheld by M. Robert and others.

2. The second case selected is this: A man affected with indurated chancre gave his mistress seven or eight chancroids, that is to say, rather large, grayish ves with cut edges and inflamed areolæ, not followed by any, even the slightest, symptoms of constitutional

disease. Such a case would, if complete, lend a certain amount of support to the "one-poison" doctrine, but it is not complete in some essential points. A mistress is not always immaculate, and this one might have acquired the disease in another way, though it is most probable she got it from the source M. Robert indicates; still, as this uncertainty does overhang the question, it would require further observations to determine this point alone. It does not appear, too, that the nature of the sores in the female even was tested by the lancet; they seem to have been phagedenic, and the modifying influence of this state on hard sore may almost be looked upon as proven, though their number militates against such a supposition. Lastly, there is reason to think that hard sore, under certain conditions, becomes inoculable, though the nature of the resulting lesion is obscure. For all these reasons, I think the case can scarcely be accepted as evidence.

3. In the third case a male patient, having a small chancre on the frænum, and a bubo with specific suppuration, inoculated himself from the pus of this bubo on the upper lip. The labial chancre hardened, and was followed by sub-maxillary bubo and constitutional disease. Here the same objection, that of being incomplete, attaches. A good deal of hardness may attend chancreoid, especially on the lip, while the fact of constitutional disease as a result of the labial sore has no weight, seeing that the lesion on the frænum, if capable as a secondary agent of bringing about such consequences, might have done so as a primary one. Unless, therefore, the dates of the sequence of affections were given, we could glean little from such facts.

4. The fourth observation is that of a young man contracting several chancreoids, with inflamed bubo, which, however, underwent resolution, from a woman laboring under infecting chancre and constitutional syphilis, and in his turn giving a healthy woman infecting sore and most severe after-disease. Unless this is an instance of true chancre, modified *in transitu*, I do not know what it was, but I do know that it does not in any way tally with my experience. During the last thirteen years, I have had, at the hospital, numerous cases of infantile syphilis, and in nearly every one I got, by dint of repeated cross-questioning, at something like a history of infection on the mother's side, counting, it is to be observed, negative evidence; in some, but fewer, a similar account from the father. In all the cases where a wife was infected by her husband through the medium of a hard sore contracted after marriage, or where there was reason to believe that the disease was conveyed by an absorbed chancreous induration, or by impregnation, there was either no evidence of her having had a sore at all, even when unimpregnated at the time of reception, or a narrative of a solitary sore, or papule, giving so little inconvenience as to awaken no suspicion; it was very rare to find that so much discomfort had been occasioned as to call for medical aid. This result exactly tallies with that of private practice; whereas in every case of chancreoid contracted by a wife infected after marriage, she applied for relief on account of the primary affection; in no instance did I trace syphilis in the children and constitutional disease in the wife to chancreoid on either side of the house; when these were assignable to the husband, there was always in him either hard sore or a story of one. In all the cases of soft sore contracted by the husband, and healed before marriage, no specific disease was ever conveyed to the wife, even when no treatment was adopted to avert it. In several instances of hard sore acquired by the husband before marriage, the most persevering use of specifics entirely failed to

guard the wife from infection, and in some of these cases hard sore was generated in her. Consequently, making all allowance for reversal of sexes, I feel rather sceptical about such evidence of the generation of chancroid from chancre.

M. Fournier, who has investigated this part of the subject with extraordinary care, traced seventy-two cases of infection to the person who gave it, and in every instance where he followed the course of hard sore, found it was due, in all cases at least where the person giving the disease had not had syphilis before, to a lesion of the same nature.

Some of M. Fournier's\* cases are very strong. In one, a woman with hard sore gave this form of disease to three men; another woman did the same thing; in another, six men were collected together, who had very likely been infected by the same person, and they all six had hard sore.† He, however, considers‡ that a person who has had syphilis may contract an infecting sore under the guise of soft sore, and yet convey hard sore to another person. §

There is a good deal more evidence to the same effect, only some of which I can quote. Dr. Bumstead, for instance, says, || that in a somewhat extended field of observation during ten years of practice he has never seen an interchange of the two species of chancre, and that he can recall fourteen cases—six of simple and eight of infecting chancre—in which the transmission of each in its kind was unquestionable. Other carefully observed cases exist, and to these I think due weight should be assigned, but at the same time I exclude all positive conclusions, such as those of M. Diday, who tells us ¶ that “infecting chancre can, in a person who has not had syphilis, only produce infecting chancre,” and that “simple sore never begets anything but simple sore,” and along with them a good deal of evidence from the writings of the French dualists.

5. The fifth case is that of three young men who were infected by the same woman, two of them with hard chancre followed by constitutional disease, and one with pultaceous phagedenic chancre, only yielding to a long course of iron. I confess myself at a loss to see what bearing such a case has upon the doctrine of unity; it may be taken as evidence that phagedena can modify hard sore, but to that I consider its influence restricted.

a, b. I now turn to the selections from M. Robert's theorems, the first of which is that the pus of an indurated chancre is inoculable on the patient himself, and that if we fail two or three times we may on the third or fourth succeed in reproducing the characteristic pustule. Let me hope it is no offence to say that this argument may as well be given up, and that it will not hold water. There is often no pus secreted by an indurated sore up to the time of repair, the very period when soft sore ceases to be auto-inoculable, and the constant recurrence of the word “pus” is calculated to make us uncertain as to the stage at which the experiments were undertaken. Mr. Lee, indeed, has succeeded in reproducing hard sore, but only before the characteristic induration had set in,\*\* and Mr. Gascoyen was equally successful in two or three instances; †† he, however, does not state the age of the chancres inoculated from. Mr. Lane also inoculated a patient from his (the patient's) own chancre and pro-

duced a soft sore,\* but here too, unfortunately, the same obscurity prevails. I at once admit having been much less successful, every attempt to auto-inoculate in the early stage having, so far as I know, failed in my hands, whereas I never observed a failure with chancroid; moreover, I have often enough not found any pus to inoculate from at the early stage, there being nothing beyond a little serum and débris. The answer to the second theorem, that this pus sometimes entirely fails to inoculate the patient, and then generally fails to convey the infection to another person, is contained in the reply to the first, and the inference to be drawn from it is that, if it prove anything, it proves a difference between the two kinds of virus.

c. The third proposition is, that a person actually suffering under syphilis can be successfully inoculated with the pus of a hard sore, and that such inoculation sometimes runs a severe course, being followed by a very inflamed pustule and extensive ulceration. It, too, is incomplete for reasons already given, and, if complete, would, however interesting in a pathological point of view, rather tell against the one-virus doctrine.

d. The fourth statement is that an indurated chancre, becoming phagedenic, can be successfully inoculated on the patient. This is very possible, but I believe the explanation is that any simple irritant, such, for instance, as savin powder, applied to the surface of a hard sore, will make its secretion auto-inoculable, ‡ and pressure seems to have had the same effect in a case related by Dr. Morgan. †

e. From the fifth theorem we learn that the pus of an infecting chancre may generate, in another person free from infection, a soft chancre without multiple bubo or constitutional syphilis. The production in public of one such soft sore tested by the lancet, and, especially if accompanied by suppurating, auto-inoculable bubo, would pretty well end the question; but till that is done I do not see how any useful purpose can be served by discussing either the nature or the course of such a lesion.

Indeed, we find not only many precautions omitted, but many statements which are calculated to make us ask whether we are not being led astray by scientific investigation. M. Robert not only succeeds in inoculating from the hard sore, but he sometimes fails with chancroid, and, what is at least equally important he finds that when the secretion from either kind of chancre does take, the sore which it sets up always follows the same course—a papule the first day, vesico-pustule the second and third, and pustule the fifth and sixth.§ He has never seen the long period of inoculation after grafting from the hard sore spoken of by Gibert, Rollet, and others, who make it amount to eighteen up to twenty-five days, and in these experiments has never produced a papule without first setting up ulceration. ||

Supposing all this to be established, it only remains to conclude that inoculation cannot be trusted, *that it is not a faithful interpreter of Nature.* The two kind of sore, when acquired by connection, do often, if not always, run a different course, and the long incubation of hard sore has occurred too often in my practice to leave a doubt of its reality. I have never indeed noticed the extreme intervals mentioned by some observers, as, for instance, fifty-six days by Dr. Jeffrey Marston, ¶ five weeks and six days, six weeks, and

and even three months by Mr. Langsten Parker;\* but within the last two years I have in addition to those not recorded noted down four cases, one of quite four weeks, one between four and five, and two of five weeks, and I cannot understand so many persons, strangers to each other, concurring in such statements if there was no foundation for them. Irrespective of this, there is a good deal of evidence showing the long incubation of hard sore, while I have not seen or read anything proving that this holds good with respect to chancreoid. Last'y, M. Fournier's account is † that we have, after inoculation from chancre, not a papule, vesico-pustule, and pustule, but simply a redness, very slight and superficial, which remains stationary for some days without its being possible to determine its character.

*f. g.* M. Robert's sixth theorem is that if we inoculate with the pus of a chancre a person suffering under chancreoid, and succeed in setting up hardness at the spot experimented upon, other co-existing chancreoids may become encircled with a passing hardness; and the seventh, that if we select a person with chancreoid accompanied by suppurating bubo, and inoculate with the pus of the latter, and that of a hard sore, leaving a distance of six or eight centimetres between the punctures, the two resulting sores often take on the same form, being sometimes both soft, sometimes hard, though it may happen that they breed true. The first fact only proves antagonism, or why did not the virus which produced the chancreoid produce the hardness at the outset? With regard to the second, I must leave it to the reader to say if he can draw any conclusive inference from it.

*h.* Next comes the statement that simultaneous inoculation, on a person free from syphilis, of simple chancre pus and hard sore secretion, generates two pustules, which almost always go through a development so identical, that it is impossible, from the mere look, to say which is which. I have already adverted to the more important part of this statement, the production of one kind of lesion from two kinds of sore; but I may be permitted to add two or three words bearing specially on the form in which M. Robert puts forth his theorem. It is very probable that two lesions beginning as pustules will run a very similar course. M. Robert is here simply accumulating evidence which shows that the pus of a hard sore may produce one without hardness. He does not recognize the fact that the typical, if not the only, lesion which results from the grafting of chancre running its natural course, is a papule, or some kindred lesion. Here too, gain, it might be urged that in his hands inoculation is not a faithful interpreter of nature, for the two kinds of sore, when derived from connection, very often run such a different course that it is quite easy, from the mere look, to say which is which."

*i.* From the ninth selected theorem we learn that inoculation of the pus of a hard sore is not necessarily followed by constitutional disease. The vagueness of this statement is rather damaging, and two or three points which should be considered separately are run together. Inoculation of such pus may fail in producing the initial lesion, and then in producing systemic disease, but inoculation which generates a papule is almost as certainly followed by constitutional infection as any one event is by another. The degree, indeed, is perhaps not the same as in syphilis derived from connection. Many years ago, in a paper read before the Medical Society of London, and reprinted in the *Edinburgh Medical Journal*, I endeav-

ored to show that the syphilis of accidental inoculation runs a very different course from that originated by intercourse; but some degree of after-effect, I believe, there always or almost always is.

*j.* Hard sore, M. Robert tells us, is sometimes followed by suppurating, with inoculable bubo, and in one case inoculation from the latter on the thigh of a healthy person generated chancre with a hard base, followed by multiple, indolent adenitis. This is the tenth theorem selected. Although during many years I have watched for such an occurrence, I have not yet seen suppurating bubo after genuine hard sore. I had under my care a case of secondary disease where suppurating in the groin certainly accompanied a small, superficial, slightly-indurated, and solitary chancre; but it appeared to have been merely sympathetic, being very small, healing within a fortnight, and leaving no particular scar. I am therefore disqualified for giving an opinion.

*k. l.* The eleventh position taken up is to the effect that the pus of a soft sore, placed upon one that is hard, may exert no influence, but that in a great number of cases it inoculates and sets up suppurating, the pus of which is highly energetic. The induction of the suppurating process causes the hardness to melt without ulceration, and sometimes brings about absorption of the hardened glands, or even retards the outbreak of secondary disease. It has already been stated that such suppurating may be caused by a common irritant, and this, I presume, is the true explanation of the fact before us. The opposite experiment, M. Robert tells us, is inert, though sometimes, if a person have soft sore, inoculation from the pus of a chancre will cause the chancreoid to become encircled with a hard base. We never, he contends, or scarcely ever, encounter the hard and soft sore on the same person, as we might expect to do if they were different. Such action on chancreoid, supposing it to have any weight, must, I submit, mean antagonism between the two kinds of virus; and this is made more probable by our author's statement that if a grafting be practised on the base of an old chancre, the hardness, though almost gone, will return, and I believe this has never been shown in the case of chancreoid. And if we ever do encounter the two forms of sore in the same individual, the usual absence of such a coincidence must count for nothing.

*m.* The last proposition chosen is that in some cases a hard sore, which has become phagedenic, spreads, inoculates the neighboring parts, and occasions acute suppurating bubo, just as soft sore does. The secretion from these inoculations can be successfully inoculated on the patient, and sets up pustules as acute as does the pus from chancreoid. Substantially this theorem has already been discussed, it being presumed that phagedæna acts here like a common irritant.

M. Robert concludes that, if there be not actual identity between the two forms of primary sore, there is, at any rate, an incontestable bond of parentage, and that both proceed from a common source, the syphilitic virus. The latter is subject to influences which impair its powers, such, for instance, as the arrival of the primary sore at the period of decline. It may be acted on in the same way by transplantation to persons already suffering from syphilis, as also from some unknown but evident state of the system; but after languishing in this unfavorable soil it may be further transplanted, be regenerated, and recover its former power.

Constitutional disposition is with him the great cause of the differences seen in sores, absolute freedom from syphilitic taint at birth being one of the strong-

\* *Ibid.*, p. 273.† *Op. citat.*, p. 111.

est of predisposing factors, and consequently a drawback rather than an advantage. He, however, admits\* that this novel view of the case is opposed to generally accepted opinion, an admission which I should say few persons will be disposed to contest. Syphilis, he holds, contracted by the parent, may protect the child, just as in after life it guarantees the individual, and he concludes by saying that infecting chancre generally springs from infecting chancre, but that in a person who has had syphilis this mode of infection brings forth soft sore as it does in some peculiarly constituted persons. Inferentially, then, his conclusions are that soft sore always springs from hard, and that the want of hardness is due to the recipient having had syphilis. This is one of the conditions necessary for the genesis of soft sore: the two others are: 1, the inoculation having been performed at the declining stage of chancre, and 2, constitutional immunity. Soft sore has a natural disposition to recover the power of infecting the constitution. Chancroid, soft sore, and hard sore are but so many manifestations of one sole virus.

Such are the arguments employed by M. Robert. I hope I have faithfully reproduced them, and know that it was my intention to do so. To me they seem, as a whole, untenable. When examined in detail, some few parts of them support the one-poison hypothesis, or, perhaps, it might better be said, are insurmountable obstacles in the way of duality; but their operation does not extend farther. They are sometimes incompatible with sound reasoning, and, I think, still oftener, with observation. The explanations of them suggested by the theory of a dual sore are an argument which I have not used, for the simple reason that I never felt quite satisfied I had such a thing as a sore of this kind before me.

Perhaps the most formidable argument, and one to which many would evidently narrow the contest, is yet to come. It has been asserted by surgeons quite able to judge, that secondary affections of the most severe type have been noticed after genuine soft sore, and these are not hasty, random statements, but the expression of careful observation. Dr. Jeffrey Marston, whose evidence was highly creditable to him, deposed to this effect before the "Committee on Venereal Diseases," † as did Mr. Longmore, ‡ Dr. John Davidson, § Dr. Thomas Nelson, who has noticed the same thing even when this form of chancre was accompanied by suppurating bubo; ¶ Mr. Samuel A. Lane, who has seen it followed by sealy and tuberculous eruptions; \* Mr. Busk, who observed papular, rupial and pustular eruptions after soft sore; \*\* and Mr. Langston Parker, who noticed constitutional affections, generally of the pustular form, after chancroid, even when it had suppurated profusely. †† Dr. Morgan, too, mentions †‡ the case of a young man, who had been in Mercer's Hospital from the first appearance of the disease, and who had severe symptoms from two soft sores, accompanied by suppurating bubo. He has also "frequently seen" multiple soft sore followed by constitutional signs, a piece of good fortune which has, I should say, not often fallen to the lot of mortals.

I suppose it is scarcely exaggerating to say that whole pages of similar evidence might be cited, but I believe that given is a fair specimen, and that it would be superfluous to go farther. I proceed, therefore, to deal with the foregoing extracts, and, hazard-

ous as it may seem, to contest the inference drawn from them. I must yet contend that they do not establish the doctrine of unity. They prove, I admit, that in some rare cases hardness does not accompany solitary infecting sore, but they do not show that it is, when in this condition, identical with soft, auto-inoculable, multiple sore; yet this must be done, or logical reasoning must halt and interpose with the conclusion that the parallel lines touch here, or nearly so, in consequence of the sudden deflection of one of them but that there is no proof of their intersecting each other. It should not be forgotten that an infecting sore may heal quickly; that hardening may come or after healing, and even after the surgeon has lost sight of the patient, and that such a train of circumstances may be followed by secondary disease. Indeed, it is a significant fact that after the surgeon's attention has been called to the point of the subsequent induration cases illustrating its occurrence turn up more frequently than was at first suspected.\* We find in the Report more than once quoted from, some of the medical witnesses dwelling rather impressively on this point.† Dr. Thomas Frazer says ‡ that he believes the induration would always be found were the patient seen from the first. Lastly, in the rare cases I have myself noticed of non-indurated sore followed by secondary disease, not only did the primary lesion differ in appearance from true soft sore, but it healed much more quickly than the latter usually does, sometimes closing spontaneously in about a fortnight, a circumstance in itself calculated to make us suspicious as to its true nature. This, too, I have some reason to think was the case in some few narratives that I have read.

While I feel no hesitation in emphatically stating that I have never seen multiple auto-inoculable soft sore followed by the typical marks of secondary disease, I at once admit that I have seen a certain degree of constitutional affection from what must have been either non-indurated infecting sore healing more quickly than usual, or chancroid, though, as stated at the very outset of this paper, I believe they must be referred to the latter, for the reason that the systemic affections differ so materially from those following chancre. From first to last, I have in about twenty years collected five of these cases. In none of them did I see the primary lesion, nor was its nature tested by inoculation. I had, therefore, to trust to the patient's description, and I need scarcely say how unreliable such authority is. Still, after making due allowance for this source of uncertainty, I could come to no other opinion than that a sore of the kind just spoken of had been the starting-point. The symptoms were in every instance mild, being with slight exceptions limited to a few papule having a history of late and very slow evolution. In two patients there was some alopecia: in two, but not the same, certain amount of sore-throat; while one had a slight attack of iritis. Four of the patients seemed to have had no suspicion that the symptoms were due to syphilis, nor could I induce one of them (the four) to go through a proper course of treatment, while mild measures in the shape of mercury and iodide of potassium seemed thrown away. The fifth patient labored under syphilophobia, and after a flying visit or two I lost sight of him, so that I could not follow up the history of the treatment.

Perhaps, then, the question really ahead of us, not so much whether the doctrine of duality as taught by Bassereau and Rollet, and at one time so very favorably received, is to be entirely subverted by it

theory of one virus, as whether infecting sore does not at times take on the look and even some of the characteristics of chancreoid. In the *Edinburgh Medical Journal* for July, 1873, I pointed out circumstances in the history of syphilis which I then thought and still think militate against such a conclusion as that involved in the doctrine of unity, in its present shape, being accepted as a satisfactory solution of the problem; but, the tide of reaction having set in toward unity, it is doubtful whether any authority would have availed to check it, experience having shown that sometimes the only plan is to let the current exhaust itself.

SIION HOUSE, KING'S ROAD, LONDON, S. W., ENGLAND.

## THE CARE OF THE EYES.

BEING QUESTIONS SUBMITTED TO

E. G. LORING, Jr., M.D.,

BY THE NEW YORK MEDICO-LEGAL SOCIETY.\*

*First question.*—"Whether bad air has any direct effect on the sight, or only mediate or resultant from other immediate bad effects?"

In considering this question I shall first assume that the real meaning of the question is whether bad air has a direct effect upon the organ of vision, and not simply as to its perceptive power, which the word sight taken literally would imply. I shall then consider the question as it actually reads, that is, as affecting the perceptive power.

I have no doubt in my own mind, and I believe it is universally admitted, that vitiated air has a direct, irritating effect on all mucous membranes, and I feel convinced from my own observation that the mucous membrane of the eye is peculiarly susceptible to its influence. This is shown by the fact that repeated attacks of inflammation of the mucous membrane of the eye, which have occurred in a vitiated atmosphere, and which have resisted all curative means, are often cured at once, and prevented from recurring, when a wholesome supply of air is obtained, all other conditions remaining the same.

I am therefore of the opinion, that bad air alone, acting as the primal cause, may set in train a series of morbid processes, which may, and often do affect, not only the working capacity and integrity of the organ, but which may lead even to its total destruction. Thus simple irritation of the mucous membrane of the eye may, and often does, pass into actual inflammation, which, increasing in violence, may proceed from part to part till the entire organ is involved, and thus the sight become impaired or totally lost.

That bad air, in the ordinary sense of the word, and including irritating gases, has a *direct* effect on the sight—that is, on the amount of perceptive power—I do not believe, nor do I understand this to be the question submitted to me; but that an impairment or loss of vision may be attributed to bad air as a direct result follows, I think, from what has been stated above.

*Second question.*—"Whether size and quality of type may cause disease of the eye?"

First, in regard to size of type. The smaller an object is, the nearer it has to be brought to the eye to be perceived.

It has been accepted by oculists that type embraced by an angle equal to 5' (five minutes) is the smallest printed matter which can be recognized by the aver-

age normal eye. According to this formula the smallest print which a normal eye can readily recognize at a distance of one foot is about  $\frac{1}{30}$  of an inch, at eighteen inches (the average distance at which the book is held by an adult), the smallest recognizable type would be about  $\frac{1}{2}$  of an inch. The normal eye should never be subjected for any length of time to a type smaller than twice this size, that is,  $\frac{1}{15}$  ( $\frac{1}{18}$ ) of an inch, and it would be better after middle life to employ a type even a little larger than this. The fact, however, that spectacles are now so commonly used removes in a great degree, by restoring to the eye its former focalizing power, the necessity of a larger type with advancing years. Young children should never hold the book nearer to the eye than ten inches, and adults never farther from the eye than eighteen inches. As soon as perfectly distinct vision at this distance cannot be obtained, and if obtained, cannot be easily maintained, recourse should be had to spectacles.

The finer, then, the type, the closer the book has to be brought to the eye, and the greater the tension or demand on the focalizing power, and the muscles which are used in bringing both eyes to bear at the same time upon the object viewed. These two acts make what is called the act of accommodation of the eye, and tension of the accommodation, that is, long-continued use of the eye upon objects brought close to it, is considered by all authorities one of the most, if not the most, fertile causes of progressive near-sightedness.

This condition may be accompanied by morbid processes, which may involve the deeper seated membrane of the eye to such a degree as to not only affect the vision, but to even destroy it. Too fine print, therefore, may be, I think, looked upon as a factor in producing eye disease, affecting not only the external, but also the internal parts of the organ.

On the other hand, too coarse print is wearisome to the eye, as it requires more exertion of the muscles governing the movements of the eye, that is, for a given amount of matter; and especially is this the case when the breadth of the page is, as usually happens, increased so as to keep the just proportion of matter on a line. This leads me to observe that usually the breadth of the page is, if anything, too great. This causes undue exertion on the part of the muscles which move the eye in a lateral direction, and is apt to lead to confusion in finding the next succeeding line. It is for this reason that the narrow form of English blank verse is so little fatiguing to the eye.

The popular prejudice in regard to the double column on a page would be untenable were it not that the same economy which restricts the amount of space also reduces the size of the type and crowds the lines together. A double-column page which is well printed and properly divided is certainly preferable to the same amount of matter extending in a single line across the entire page.

The distance between the lines, that is, from the bottom of one line to the top of the other, should be about  $\frac{1}{2}$ , or one-eighth of an inch. Nearer than this is apt to be confusing; farther, fatiguing.

The distance, however, can be considerably less in a page with a double column than in one with a single.

If a double-column page is used the distance between the columns should not be less than one-quarter of an inch.

*Quality of Type.*—The less contrast there is between an object and its surroundings the more difficult it is to see the object, and the closer it has to be brought to the eye. A faintly-printed page has therefore to be brought nearer, oftentimes very much nearer, than a

\* Read before the New York Medico-Legal Society, Feb., 1877.

well-printed page of the same type. There is nothing more wearisome to an eye than an indistinct and blurred image of a familiar object, and no more striking example of this could be found than blurred or faintly-printed type. This should be sharply cut, and what is technically called "heavy faced," in contradistinction to "light faced" type. Of the former a common example is the English; of the latter, the American.

The ink is also a matter of importance.

English ink, like the type, is vastly superior to American. The color and quality of the paper has also an influence upon the ease with which the act of vision is performed. For, while it is true that there should be as much contrast as possible between the type and its surroundings, care should be taken to avoid all glare or dazzling of the page. Pure white paper, such as is ordinarily used in this country, should not be employed, most of all when it has, as it often does in the cheaper papers, a metallic lustre with a bluish tinge. I have come to the conclusion that, as a rule, a very light, almost imperceptible, yellow tint is the best. This is known in the trade as "natural" tint, from the fact that it contains no dye whatever, and has been bleached only to a moderate degree. It has the color of unbleached cotton cloth. It is, however, expensive, as it can only be made from the best stock; still a very good imitation can be had in some of the second-class papers, at a moderate cost. The paper should be thick enough not to be transparent, should have a close, fine texture, and be free from sponginess.

From these facts I am of the opinion that, both in respect to size and quality, imperfect type may be considered as a factor in the production of eye diseases.

*Third question.*—"Whether too long and constrained attention to one object without rest or variety will cause eye-disease?"

That prolonged tension of the eyes may be the primal cause of a great number of diseases of the eye is admitted by all authorities, and the more fixed the gaze, and the narrower the field of view, the greater the danger. If it be true that continued tension of muscular and nervous force unduly exhausts the energy of any organ, it is doubly true of the eye. The nervous energy of the retina, sensitive and rapid as it is, is just as rapidly exhausted, and the act of reading would be unbearable after a few moments, if the eye did not quickly change its position from letter to letter, and from line to line. Diversity of action is as much a necessity in the case of the eye as of any other organ for an easy and lasting performance of its function. No eyes, in my opinion, should be used more than an hour at the farthest in the act of reading or writing without an interruption of the gaze, and it would be better if several, if not many interruptions should take place in the same time.

This usually happens in the case of adults for some reason or other; but children, in order to complete their tasks in an allotted time, are often compelled to use their eyes, without sufficient interruption, by the hour together. It would be impossible, and out of keeping with the condensed character of these remarks, to enumerate here all the diseases which may arise from prolonged tension of the eyes on near work; but there is an affection produced by it which is so frequent in its occurrence, and so unfortunate in its results, that I cannot refrain from saying a word in regard to it, using substantially the language of one who is the greatest authority on the subject instead of my own. Professor Donders thus remarks:

"The distribution of near-sightedness chiefly in the cultivated ranks points directly to its principal cause:

tension of the eyes for near objects. Respecting this fact there can be no doubt.

"Three factors may here come under observation:

"1st, pressure of the muscles on the eyeball in strong convergence of the visual axes; 2d, increased pressure of the fluids resulting from accumulation of blood in the eyes in the stooping position; 3, congestive processes in the eye which, tending to softening, give rise to extension of the membranes. Now in connection with the causes mentioned, the injurious effect of fine work is by imperfect illumination still more increased.

"To this it is to be ascribed that in schools where, by bad light, the pupils read bad print, or write with pale ink, the foundation of near-sightedness is mainly laid, which, in fact, is usually developed in these years."

*Fourth question.*—"Whether the angle at which the light strikes the eye is important, that is, ought it not to fall, not full in the face of the child, but first on the book, or work, and be reflected into the eye?"

Before answering this question precisely as it now stands, I should like to premise it by making the general assertion that not only is the direction in which the light comes important, but also its quantity and quality. Reduction in illumination is, as a rule, precisely equivalent to a reduction in the size of the object. Therefore, the less the light, the nearer an object has to be brought to the eye, and the greater the strain in the act of vision.

It is impossible to fix with any scientific exactness just the size that a window should be to give sufficient light for visual purposes, since this must vary with the exposure and surroundings of the room; but it has been reckoned in Germany that for a class-room containing twenty persons, there should be at least 4,000 to 6,000 square inches of glass, which would give to each scholar, from 200 to 300 square inches or what would be represented by a pane of glass from 14 to 17 inches square. Such a room as this would be sufficiently lighted in any part. A room 20 feet square should not contain less than 70 to 80 square feet of glass, and it may be laid down as a rule that too much light cannot be obtained in a room, as an excess of glare can be guarded against by artificial shades if properly applied.

More light enters a room from the same amount of glass from the south than from the north, and southern, south-eastern, or south-western exposure is better than a northern, north-eastern, or north-western, especially for class-rooms, and this, too, simply in regard to the amount of light, and independent of the purifying influences of direct sunlight.

That a north room is better for the purposes of the artist is due to other causes, and does not affect the general rule.

The light should not come from directly in front, and especially is this the rule when artificial light is used. For when the light comes from directly in front of the person, the pupil of the eye becomes unduly contracted, which is equivalent to reducing the quantity of light, since less light enters the eye from the object viewed, while the eye is exposed to too much light reflected from the surrounding objects as if from the direct rays from the source of illumination.

Neither should the light come from directly behind as the object then lies in the shadow of the body. Nor yet from the right side, because in writing the shadow of the hand falls across the page, and a moving shadow over a lighted surface not only reduces the quantity of light and leads to a stooping position, but it is also more annoying to the eye than a uniform reduction in the illumination of even a greater degree.

The best direction for the light to come is from the left-hand side, and from rather above, than below the level of the head. Windows, therefore, should not run down too near to the floor, as they often do in class-rooms and offices.

I cannot agree with the opinion, often expressed, that the best direction for the light to come from is from directly above.

I cannot refrain from adding, in this connection, the conclusion, founded on Dr. Cohn's elaborate investigations in regard to the near-sightedness among school-children from Germany. He thus formulates it: "The narrower the street in which the school-house was built, the higher the opposite buildings, and the lower the story occupied by the class, the greater the number of near-sighted scholars."

I should then, from these considerations, say that the angle at which the light strikes the eye is important, and that it ought not to fall in the face of the child, but first on the book or work, and be reflected into the eye.

## Progress of Medical Science.

**TREATMENT OF MEMBRANOUS CROUP.**—Dr. Walcher claims to have had great success in the treatment of membranous croup, both in its primary form and in the form which he regards as secondary to diphtheria of the pharynx. He employs the alcoholic tincture of eucalyptus globulus. Prof. Gubler and Dr. Gimbert, of Cannes, have shown that eucalyptol, the active principle of the eucalyptus, has a special action on chronic catarrhs, with muco-purulent secretion, especially when located in the lungs, and that the resinous principle is chiefly eliminated through these organs. Dr. Walcher employed it with benefit in doses of from  $2\frac{1}{2}$  to 5 drachms per diem, in cases of chronic bronchitis in old people, and in a case of pulmonary gangrene that recovered. He then tried it in several cases of croup, and it succeeded beyond his expectations; in one case a cast of the entire trachea and of the first and second bronchial bifurcations was coughed up, and the patient, a child five years of age, recovered. He has now discarded local applications, and orders an ounce of the tincture of eucalyptus with three ounces of syrup, a teaspoonful of the mixture being given every hour. The children take it readily, and if given slowly, any diseased part in the pharynx will be sufficiently impregnated with the medicament. A mild emetic of ipecac is given occasionally, if the patient be strong enough to bear it. Cold drinks are given to relieve thirst, and cold applications are made to the head, if there is much congestion. The child's strength is to be kept up by proper nourishment; the alcohol contained in the above mixture is serviceable in this connection. Dr. Walcher has given five drachms and more of the tincture of eucalyptus per diem to a child five years of age, and has never known any bad symptoms to be produced by it. Dr. Siegen thinks that it is indicated in all febrile affections of the respiratory organs, and especially in whooping-cough.—*Gazette Médicale de Strasbourg*, Feb. 1, 1877.

**TREATMENT OF HYSTERICAL ANÆSTHESIA.**—At the meeting of *Société de Biologie*, on January 13th, M. Charcot drew attention to the investigations of M. Berg, on the treatment of certain hysterical affections, especially anæsthesia, by what he calls metallotherapy. Then, for instance, a number of twenty-franc pieces, bound together, are applied to an anæsthetic limb, the

sensation will be restored at the end of fifteen or twenty minutes. The phenomena that are observed are the following: Augmentation of the temperature, dysæsthesia, and finally complete return of sensibility, reappearance of the muscular power, progressive extension of the sensitive zone to a wider space around the metal, or even to the entire limb, and finally dilatation of the capillaries. The last is demonstrated by pricking the anæsthetic points with a pin; before the application of the gold this causes no bleeding, but after the application it is followed by considerable flow of blood. The sensibility, after its re-establishment, remains for a few hours, sometime for an entire day. M. Charcot has seen the same results follow the application of the gold in anæsthesia of many years' standing due to cerebral lesion. Hence, Trousseau erred when he insisted that metallotherapy might be used as a means of settling the diagnosis of hysteria. The phenomena are undoubtedly electrical in nature. On the one hand the metallic applications produce currents, and on the other a battery, producing currents of the same intensity, causes exactly the same effects. The sensitiveness of patients to one metal, as gold, or zinc, or copper, to the exclusion of the others, seems to depend on the differences in the intensity of the currents produced by the different metals. Thus, a patient who is affected by the current produced by copper will be unaffected by the weaker current produced by gold, but will be affected by a current from a battery equal in intensity to that produced by the copper; *vice versa*, a patient affected by gold will also be affected by an equally weak current from a battery, but will be unaffected by copper, or currents equal in intensity to those produced by copper.—*Gazette Médicale de Paris*, Feb. 3 and 10, 1877.

**THE LATERAL MOVEMENTS IN THE KNEE-JOINT IN CASES OF WHITE SWELLING.**—These movements have been ascribed by surgical writers exclusively to alterations in, or destruction of the peripheral ligaments. M. Montard-Martin, however, has had opportunities of observing four cases which presented this sign during life, and in which the autopsies showed that the ligaments retained their normal strength, while the cartilages were greatly altered, or even absolutely destroyed. The first case was one of suppurative arthritis, consecutive to osteomyelitis, and the lateral movements during life were attended by crepitation. The autopsy showed destruction of the cartilages, but the anterior, posterior, and lateral ligaments were healthy; only the accessory fibrous bands which form the capsule presented fungous growths. The three other cases were instances of white swelling, and in none of them was crepitation present during life. In two of these cases the internal surfaces of the capsular ligaments were covered with fungous growths, and in one there was an opening through the internal lateral ligament into the bursa that separated the gracilis from the knee-joint. In all three cases, however, the true ligaments preserved their normal thickness and strength; they were neither relaxed nor softened. On the other hand, the cartilages were either thinned and atrophied, or were softened, ulcerated and destroyed in part, so that the space between the bones was incompletely filled out. In the first case, both cartilages and fibro-cartilages had entirely disappeared. These changes in the cartilages are quite sufficient to explain the abnormal lateral mobility in one of the cases the crucial ligaments were still intact. It is quite possible that in all these cases, if life had been prolonged, the abnormal movements

would ultimately have produced stretching and disorganization of the true ligaments. If these observations are confirmed by further autopsies, lateral mobility will become an important indication for the production of ankylosis, or for amputation or resection.—*Le Progrès Médical*, Feb. 3, 1877.

**DOUBLE PILEGMATICA DOLENS WITH DISEASE OF THE SACRUM AND COCCYX.**—At a recent meeting of the *Société de Biologie* M. Dumontpallier presented some specimens which tend to throw some light on the origin of this obscure disease. A young girl had reached the twenty-first day of a typhoid fever, when suddenly the left lower extremity became painful, oedematous, and of a blue and white color. Two days afterwards the left leg and thigh were similarly attacked. The case terminated fatally, and at the autopsy the usual lesions of typhoid fever were found, and in addition coagulation of blood in the primitive iliac veins, prolonged on both sides into the crural. M. Dumontpallier then examined the pelvic veins, and found that the sacrum and coccyx were the points of departure for the coagulation in these vessels. Those that supplied the sacrales and their branches were filled with old clots, while the primitive iliacs and the crurals contained recent ones.—*Gazette Obstetricale*, 4, 1877.

**PURULENT INFLAMMATION OF THE UMBILICAL VEIN IN INFANTS.**—Dr. Roper has reported two fatal cases of pyæmia in infants. In the first, the only abscess found during life was in the neighborhood of the right deltoid muscle. After the separation of the cord on the fifth day, the parts about it continued red. Death occurred on the nineteenth day. After death general peritonitis was found, and the umbilical and portal veins were inflamed and full of pus. No pyæmic deposits were found anywhere. About the same time he attended a primipara, and applied forceps. After a week the child developed abscesses in the wrists and feet, and the right lower limb became gangrenous as far as the hip. It died on the fourteenth day. The only lesion in this case was purulent inflammation of the first inch of the umbilical vein. In another instance reported by Dr. A. W. Edes, the child developed abscesses about the end of the first week of life. Abscesses formed in the right shoulder and right lower limb. Death took place on the eighth day. The post mortem examination showed local peritonitis, inflammation of the umbilical vein, which contained pus; there was also plugging of the right femoral vein. This case also was held to be an instance of pyæmia.—*Obstetrical Journal*, Feb., 1877.

**CASSIA ALATA IN THE TREATMENT OF RINGWORM.**—Dr. Tilbury Fox, of London, writes to the *British Medical Journal* that he tried the efficacy of this Indian remedy some ten years ago, and though he found it of some value, thought it had no special advantages over other parasiticides. He also holds the same opinion in regard to goa-powder, which has a reputation in the treatment of ringworm. Dr. Boulton, however, regards the latter as a specific.—*British Med. Journal*, Feb. 3, 1877.

**EXCISION OF THE KNEE-JOINT BY A NEW OPERATION.**—Mr. Treves, of Margate, gives a record of eight cases in which he has performed this operation, and with only one fatal result. His success he attributes in part to having secured and preserved immobility of the limb, in part to careful after-dressing. The plan of the operation is as follows: A semilunar incision about three inches in length is made on each side of the joint; then the lateral ligaments are divided

and the tissues deflected until the synovial cavity in front is opened. If there are adhesions here, they are divided. A wide director is then passed behind the joint in front of the posterior ligaments, and with a narrow bistoury the crucial ligaments and any adhesions between the bones are divided. Next a metal retractor is inserted in front of the bones, to prevent the tissues from being injured. The blade of a butcher's saw is used to take off a thin slice from the joint-ends of each bone. The chief advantages he claims are: 1. Decided improvement in the appearance of the limb. 2. Greatly increased power of extension. After ordinary excision, extension is often feeble from the divided and shortened extensor tendon. With this operation they are able to lift the leg before union is firm. 3. The extensor tendon being attached to the tibia in front, whilst the posterior ligament is intact behind, the bones are not so loose, and the tibia is not so likely to get displaced. 4. The sawn surfaces, being in a measure protected, unite more kindly than under the usual operations.—*British Med. Journal*, Feb. 3, 1876.

**THEORY OF THE ACTION OF NITRITE OF AMYL.**—Dr. Mader is of opinion that the dilatation of the vessels which follows the use of nitrite of amyl is referable to the action of certain vaso-motor centres of the spinal cord rather than to a direct paralysis of the muscular coat of the vessels. In the latter case, he argues, we should have symptoms of hyperæmia of the lungs, of which there is no indication. Secondly, a directly paralyzing influence would pre-eminently affect the heart; and this is not so. Thirdly, there would necessarily be paralysis of the vessels of the whole body. Fourthly, the production of congestion of the head is not peculiar to this drug alone, but also occurs with alcohol and the ethers, to which it is allied, and their action on the nervous centres cannot be doubted. Fifthly, he made this experiment, which he considers disproves the directly paralyzing action of the nitrite. He enclosed the hand and forearm of an anæmic girl in an air-tight rubber sack, into which the nitrite was then introduced without producing the slightest redness. Dr. M. thinks it is quite open to question whether the action of nitrite of amyl in dilating the vessels is really that to which it owes its therapeutic effect, and is not rather a disagreeable accompaniment, while its useful effects are due to the production of a transitory narcosis analogous to that produced by alcohol, ether, or chloroform.—*Bericht der k. k. Krankenanstalt Rudolph Stiftung, in Wien*, 1875.

**CROTON CHLORAL.**—From trial of it in some forty cases, Dr. Mader has found croton chloral a useful hypnotic, in doses of from grs. 7½ to grs. 22½, sometimes answering in both medical and surgical cases where morphia or hydrate of chloral was contraindicated. He did not find it act satisfactorily, either to relieve cough or to cure neuralgia, even if it did produce sleep.—*Bericht der Rudolph Stiftung*, 1875.

**TINCTURA CORTICIS CRO.**—This tincture, prepared from a Peruvian bark, has been used by Dr. Mader as a remedy for diarrhoea in some thirty cases. It is given in doses of ten drops once in two hours up to as high as ninety drops in a day. Owing to its acrid taste it should be given diluted with water, and extract of lignorce should be added. It proved itself a good astringent in the cases mentioned, but not equal to opium. It will require further experiment to determine whether it will have special value in the diarrhoeas of children, where it is undesirable to give opium.—*Bericht der k. k. Krankenanstalt Rudolph Stiftung, in Wien*, 1875.

# THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

W.M. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, April 14, 1877.

## THE PROSPECTIVE PHARMACOPŒIA.

Two pamphlets\* are before us, both devoted to the consideration of the same question: How and by whom shall the next Pharmacopœia be constructed?

We believe that it is quite universally conceded by those who have given the subject special consideration that the Pharmacopœia of 1873 is a pretty poor affair, and that the construction of a better one is one of the most pressing and important subjects before the profession at the present moment, for upon a good pharmacopœia depend our best hopes of successful therapeutics. We shall therefore consider in some detail the plans advocated in the pamphlets under notice.

Dr. Squibb proposes that the American Medical Association shall at its next meeting recommend the formation of a "Pharmacopœial Council," who shall have the entire charge of the work of constructing and bringing out the next Pharmacopœia. This council is to be composed of five members, of whom one shall be appointed by the American Medical Association, one by the Surgeon-General of the U. S. Army, one by the Surgeon-General of the U. S. Navy, and two by the American Pharmaceutical Association. Suitable provision is made for the supply of any vacancies that may occur in the *personnel* of the Council. This body, aided by additional experts, shall prepare and publish, as soon as practicable, a revised pharmacopœia, which shall include not only specific directions for compounding the official preparations, but also much additional matter of value to the apothecary, such as practical manipulative details, tests for the quality and purity of drugs, etc. This Pharmacopœia shall be thoroughly revised after a certain number of years. In the meantime, however, the Council shall publish

an annual fasciculus or supplement, containing notices of such new matters as may be expedient. The copyright of the book is to be vested in the American Medical Association, and the profits from its sale to be expended upon the experts employed by the Council. This is a brief outline of Dr. Squibb's plan, and for details we must refer to the pamphlet itself.

It will be seen that if this plan is carried out the long-honored U. S. Dispensatory will be no longer required, as the Pharmacopœia itself will contain the essential matters which, heretofore excluded from the latter, have rendered the former a necessity. As a matter of economy this is to be desired. Comparatively few physicians possess either the present Pharmacopœia or the Dispensatory. The first is of very little use to them, and the latter is quite expensive. The cost of the Dispensatory is in part due to the fact that it is a disquisition upon the British as well as the U. S. Pharmacopœia, and contains a great deal of matter that may be interesting reading in England, but which is of little real value here. This extraneous matter most physicians will not pay for, and druggists would not if they could help themselves. A new Pharmacopœia, therefore, which included more than the old one, and less than the Dispensatory, would be a boon to many physicians whose pockets will not permit the indulgence of extravagant outlay. It is highly probable, therefore, that a four or five dollar book would go into many hands that desire and need it, and which are not reached by the present ten-dollar Dispensatory.

The present Dispensatory being the only book upon the subject of which it treats, is necessarily the best one. That it is the only one is due in part to the fact that the book has been made one of great value (to those who can afford to possess it), through the indefatigable industry and the skill of its honored authors, Drs. Geo. B. Wood and Franklin Bache. All things must have an end, and if our next Pharmacopœia is constructed upon the old plan, an explanatory Dispensatory founded upon it must be entrusted to new hands, which may or may not perform the task as well as it has been performed in the past. We will then have, as before, two books, neither of which will reach the majority of the profession. We confess, therefore, that we are favorably impressed with Dr. Squibb's plan, and we believe that its practical details can be carried out with success, and to the satisfaction of the profession at large—that is, to those whose personal interests would not be impaired by the change.

Dr. H. C. Wood objects *in toto* to the proposed plan, believing that it is much better to continue in the old way; that our last Pharmacopœia is a very good one; and that the next one, if constructed under the same auspices, will be good enough, provided it is accompanied by a Dispensatory, to be edited, in all probability, by himself. We shall consider some of Dr. Wood's arguments in our next.

## CHEAP MEDICAL EDUCATION.

OUR correspondent from Wisconsin, with an enthusiasm which is perhaps worthy of the cause, again volunteers to set us right upon the subject of cheap medical education. It appears to us, however, that the questions he asks almost answer themselves. Except that he is avowedly a champion of the other side, we should believe that he entirely agreed with us. At best, we can do no more than excuse ourselves for being misunderstood.

The burden of objection on the part of our correspondent is simply, that while the larger colleges may seem to teach for money, the smaller ones certainly do not. Assuming also that medical instruction is not merchandise, and that there is a higher incentive than mere money for the cheap colleges to continue their work, we are almost persuaded that such institutions are the best. But we do not see why it is necessary to go so far to prove that there is still some honor in the profession. We confess that we hardly doubted the fact; certainly we are sorry that we conveyed the impression that a professor in a cheap college was dishonorable or void of conscience because he gave the students their money's worth.

If he does more than his duty "regardless of price," he has an extra consciousness of good work performed which the higher-priced teachers can never feel. But as virtue always brings its own reward, so much the worse perhaps for the high-priced professor, and so much the better for the poor student. Notwithstanding all this, we are not yet convinced that students attend Bellevue or the University more for the prestige of the thing than for any superior advantages they may enjoy. The fact that some of the graduates of these schools, who occasionally straggle in the neighborhood of our correspondent, are found wanting, is bad enough; still, these men are not without hope, when it costs so little to obtain first-class instruction.

For the sake of the argument, we are somewhat disappointed to learn that our critic founds his assertions upon the personal observation of one particular faculty; as such is, probably, his alma mater, we have a right to look upon his point as much in the light of an exception as he has to make it the rule.

No one is willing to say that the teachers in our cheap schools are not thoroughly competent. We never questioned the fact. Indeed, we believe that their talents are first class; we only object to their being hidden under so small a bushel.

## THE NEW YORK HOSPITAL SCHEME.

THERE is a strong feeling of indignation in the profession against the recent course taken by the Governors of the New York Hospital in the establishment of their out-door department. Medical men who are dependent upon their practice for their living have a just right to complain. In another column we publish two of the many letters upon the subject, which we have received.

## Obituary.

## WILLIAM WOOD,

NEW YORK.

WILLIAM WOOD, the well-known medical book publisher, died suddenly of cardiac disease on the morning of April 9th, aged eighty years.

For nearly fifty years, and up to his retirement in 1868 from the firm of William Wood & Co., he was actively identified with the interests of medical literature in this country. As a publisher of medical works he was a recognized leader, and will long be remembered as one of the pioneers in this special branch of the trade. His position as such brought him in contact, from time to time, with the leading medical men of the country, with whose early struggles in authorship he sympathized, and in whose successes he gloried. Always upright in his dealings, cordial in manner, and firm in friendship, he earned for himself the respect and esteem of all who knew him.

He was of Quaker descent; his father, Samuel Wood, came to this city from England in 1803, and the small book-shop which he established at No. 362 Pearl street was the foundation of the present publishing house of William Wood & Co. In 1822 William Wood was admitted to partnership with his father and elder brothers. The business increased rapidly, and a large five-story building was put up on the old Pearl-street lot. The firm, influenced by the tastes of its younger member, then commenced the publication of medical works. As a consequence, the store on Pearl street soon became popular with the profession, and was the resort of its most prominent members. Here Francis, Hosack, Mitchell, Mott, and Stevens would meet to talk over their triumphs, discuss their plans, and learn of the new publications in which they were interested.

Samuel Wood died in 1844, but the business was continued in Pearl street until 1856, when the firm moved to No. 389 Broadway. In 1862 William Wood moved to No. 61 Walker street, and soon afterward associated with him in business his son William H. S. Wood, who is now the senior member of the present firm of William Wood & Co.

In 1865 Mr. Wood established the *MEDICAL RECORD*, the pecuniary success of which has been the result of the rare business tact with which it has been managed from the start. His encouraging confidence in the editorial management of this journal is a grateful remembrance for the writer, and almost irresistibly prompts the utterance of sentiments which are sacred to the memory of personal friendship.

Since his retirement from business, Mr. Wood gave his almost undivided attention to the promotion of the interests of the Society of Friends, of which he, for a long series of years, was a very active member.

## WILLIAM A. MUHLENBERG, D.D.,

NEW YORK.

THE Rev. Dr. Muhlenberg, the founder of St. Luke's Hospital of this city, died April 8, in his 81st year. Graduated in 1814 from the University of Pennsylvania, he was ordained a deacon in the Protestant Episcopal Church by Bishop White, of Pennsylvania, and immediately afterward entered upon the duties of Assistant Pastor of Christ Church, Philadelphia. In 1821 he became the Rector of St. James' Church in Lancaster, Penn., where he remained six years. From

Lancaster he removed to the village of Flushing, Long Island, and established there the Flushing Institute, a school designed for the education of boys and young men in the Protestant Episcopal Church. In 1836 the institute was removed to College Point, Long Island, and was re-christened St. Paul's College; he remained its principal until the year 1845. In that year he came to New York to assume the Rectorship of the Church of the Holy Communion, situate on the corner of Sixth avenue and Twentieth street, which had been built, one may say, for him, by his sister, Mrs. Mary Ann C. Rogers, the widow of John Rogers, Esq., of New York.

Dr. Muhlenberg also established the House of Mercy and its accompanying Sisterhood, the first of its kind in the United States. The lady who was the first to enter the Sisterhood of the Church of the Holy Communion is at the head of the Sisterhood of St. Luke's Hospital at the present time.

The charity which has made Dr. Muhlenberg's name most widely known is undoubtedly St. Luke's Hospital. It grew from contributions of private individuals with such rapidity that its originator might readily be supposed a very energetic and efficient demander of alms. Such, however, was not the case. Dr. Muhlenberg was painfully shy in approaching people, and modest to a fault. It was in 1846 that he took up in his church the first collection for St. Luke's Hospital and gathered in the sum of \$33. From this amount the fund swelled till at present his hospital occupies nearly an entire block on Fifth avenue and Fifty-fourth street, the buildings having been erected and formally opened by the year 1858.

Dr. Muhlenberg was installed as Rector of the chapel attached to the hospital, and took up his abode in the building itself, where he has remained until his death. Not content with succoring the sick, in 1864 he planned another charity which should save the young children of the city from misery and vice, and soften the remaining years of the aged and infirm. The plan was carried out in the little community of St. Johnland, on the north shore of Long Island, about forty-five miles from the city. Sick and crippled children, and those likely to be brought up in ignorance and destitution, are received in a children's home. There are appropriate buildings for old people of both sexes, a library and numerous other buildings, some of them being special gifts from individuals. Dr. Muhlenberg had most remarkable executive talents. Whatever he attempted was made a success.

Dr. Muhlenberg was the author of many well known hymns. One is the famous "I would not live away, I ask not to stay." Another is that beginning, "Shout the glad tidings, exultingly sing;" and still another, "Like Noah's weary dove." In 1823 he published a compilation of religious poems called *Church Poetry, being Portions of the Psalms, in Verse and Hymns, Suited to the Festivals and Fasts, from various Authors*. In 1852 appeared a second, entitled *Music of the Church*; and in 1858 *The People's Psalter*.

**BRAVAIS' DIALYZED IRON.**—This preparation is recommended by the *British Medical Journal*. It is said to be a neutral solution of the peroxide of iron in the colloid form, all acid having been extracted by dialysis, and may be considered as the nearest approach yet made to the form in which iron exists in the blood. It is almost tasteless, has the good effects of iron without producing constipation, and has also the further advantage that it does not blacken the teeth.

## Reports of Societies.

### NEW YORK PATHOLOGICAL SOCIETY.

*Stated Meeting, March 14, 1877.*

DR. E. G. JANEWAY, PRESIDENT, IN THE CHAIR.

#### EXTIRPATION OF RECTUM.

DR. BRIDDON presented a specimen of extirpated rectum. He remarked that in November, 1876, he had exhibited to the Society a portion of rectum extirpated for cancer. It had been removed from a woman in the hospital department of the Colored Home. The disease commenced immediately above the internal sphincter, and extended two and a half inches up the gut, terminating in that portion upon which the peritoneum was reflected. The patient did very well after the operation, but finally succumbed from thoracic disease. He had expressed the opinion some time ago that there was a return of the disease in the cicatricial tissue, between the margin of the perineum and the contracted end of the rectum; the specimen in question, which had been removed two or three days before the meeting, exhibited, however, but little trace of the disease in that precise locality, but showed that it had extended to some of the glands above. The distance from the cicatrix to the retracted rectum was one and a half inches.

He then read the history of the autopsy, for which he was indebted to Dr. Wm. Kelley, house physician:

Eliza Walker. Autopsy thirty hours post-mortem. Rigor mortis marked. Body markedly oedematous; not very well nourished. Brain not examined. The right pleural sac was about two-thirds filled with a serous fluid. The diaphragmatic, costal, and visceral portions of both pleurae were studded with tuberculous deposits—the right more so than the left. The left pleural cavity contained a small amount of fluid. Right lung was very much compressed, and in a state of carnification; numerous tuberculous deposits were found scattered throughout. Left lung was of normal size, and contained in its apex a patch of catarrhal pneumonia undergoing cheesy degeneration; at the centre of this a small cavity existed. In addition to a number of similar spots of small size, numerous tuberculous deposits were found. Heart normal. Spleen somewhat diminished in size, otherwise healthy. Liver smaller than normally; was very soft, and the seat of extensive fatty degeneration. A grayish-white mass, about as large as a goose egg, and a number of smaller growths, probably gummy tumors, were found. The largest one was softened, and had undergone cheesy degeneration; the others were quite firm. No secondary cancerous deposits could be detected. Kidneys were lobulated; otherwise healthy. The pelvic viscera were removed and examined. Bladder healthy. Uterus and appendages normal. Some slight peritoneal adhesions existed in Douglas's cul-de-sac.

From the anus to the lowest portion of the intestine (a distance of one and one-half inches) a pseudo-mucous membrane had formed, but no return of the morbid growth (removed on November 20, 1876) could be detected. At the junction of the intestine with the pseudo-mucous membrane a slight constriction existed.

In the cellular tissue adjoining the upper posterior portion of the false mucous membrane, a few enlarged lymphatic glands were found. A fistulous communication existed between the rectum and the vagina at the posterior commissure.

Dr. Mason asked how much control the patient had over the movements of her bowels.

Dr. BRIDGON answered that after the morphine was diminished she had a diarrhoea for several weeks, since which time she would be compelled to evacuate her bowels as soon as the desire to do so manifested itself.

#### ADENOMA OF SOFT PALATE.

Dr. A. H. SMITH presented a tumor removed by operation from the soft palate of a patient who had come to him from the interior of the State with a diagnosis of malignant disease. The growth projected but slightly into the mouth, but the whole of the space behind the velum on the right side, and the adjacent pharynx was occupied. The growth was about the size of a butternut. About two years ago the patient first discovered a small growth in the soft palate, which gradually increased until it became the size of an almond. At that time the physician who saw the case advised the application of caustic. The result was the formation of an eschar which, when separated, gave issue to a considerable amount of gray mucus-like fluid. The wound healed, and for a time it seemed as if the difficulty had entirely disappeared. A year ago last December the growth again commenced to show itself, and continued to increase until Dr. Smith saw him. He formed the opinion that the tumor was of that variety first described by Nélaton as adenoid. Extirpation was advised, and performed accordingly. The operation was very simple, and consisted merely in the division of the mucous membrane over the tumor, and shelling it out with the finger pressed from behind. The only embarrassment was in consequence of the cicatrix, which had to be divided with the scissors. The patient during the operation was placed in Ross's position, with the head over the edge of the table. The recovery was rapid and complete.

Dr. Smith remarked that the clinical features of these tumors were slowness of growth, painless character, freedom from attachment to mucous membrane, and their non-liability to pass beyond the raphe of the soft palate.

#### EMPHYEMA AND PYO-PNEUMOTHORAX.

Dr. JANeway presented a specimen of emphyema with pyo-pneumothorax, and read the following history:

Bridget Nolan, aged 23, Ireland; admitted January 4, 1877; family history unimportant; denies drink and venereal; had diseases of childhood; had one child, which was delivered without instrumental interference four months ago; since this time she has suffered from pelvic and lumbar pain, pain on defecation, and dysmenorrhœa. For the relief of these symptoms she entered this hospital. Examination revealed a retroverted and retroflexed uterus. The uterus is fixed; patient's general health quite good.

Jan. 14.—Yesterday patient was in the amphitheatre. In the evening she had a severe chill, followed by pain in the right chest of a lancinating character. These symptoms were soon followed by febrile movement and cough, without at first expectoration. This A.M. the temperature is 103°; P.M., pulse, 104; respiration, 30; temperature, 102½. Ordered ℞ quin. sulph. gr. x. t. i. d., and sufficient morphia to keep her free from pain.

Jan. 15.—The physical signs of consolidation are evident over the upper portion of the lower lobe of the right lung. Patient to-day expectorated a few rusty sputa.

Jan. 17.—The signs of consolidation have extended over the entire middle and lower lobes. Is having quin. sulph. gr. x. t. i. d.

Jan. 23.—This morning a few subcrepitant râles are heard over the consolidated lobes. Patient is perspiring profusely. Is still taking the quinine.

Jan. 28.—Is apparently improving. The physical signs indicate nearly completed resolution in the affected lung. Quinine discontinued.

Feb. 9.—Still complains of feeling weak. Has some dyspnoea. Has very little appetite, and eats scarcely any food. Physical examination this evening reveals flatness over the entire right chest, and bronchial respiration over a small space at the summit. Elsewhere respiratory sound is absent. The hypodermic needle was introduced, and a syringeful of pus withdrawn.

Feb. 10, A.M., temp. 99½°; P.M., temp. 102°.

To-day patient is suffering from dyspnoea to a considerable extent; complains of feeling very weak; ordered whiskey ʒss t. i. d. About 4:30 it was deemed advisable to aspirate the chest. This was accordingly done, and ʒlx. of pus removed. Toward the last gas was withdrawn with the fluid. The needle was removed, and on auscultation the succussion sound was heard. Patient appeared to suffer no inconvenience from the operation.

Feb. 11, A.M., temp. 100°; P.M., temp. 100½°.

Patient feels considerably better than before operation. On auscultation, amphoric respiration and metallic tinkling are heard posteriorly. Stimulants and occasional doses of quinine are given.

Feb. 12, A.M., temp. 98½°; P.M., temp. 99½°.

March 2.—Since last note the temperature has ranged between 99° and 102°. The fluid in the cavity has considerably increased in quantity. Is quite weak and takes little food.

March 3 to March 8, temp. 99–101°.

March 9, a free incision was made in the seventh intercostal space in the infra-axillary region, and about ʒxxiv. of pus escaped. The operation was followed by no unpleasant symptoms. This evening the cavity was washed out with dilute solution of carbolic acid.

March 10, A.M., temp. 101°; P.M., temp. 99°.

Patient passed a good night, and this morning seems quite bright. The pleural cavity is washed out twice a day.

March 11, A.M., temp. 98°.

This morning the patient appeared as well as she did yesterday. About 11 o'clock the pleural cavity was washed out. Just at the completion of the operation patient suddenly exclaimed, "Oh, doctor! my breath!" The heart's action ceased immediately. The pupils dilated widely, and with a few gasps patient died. External and internal stimulation were resorted to, and artificial respiration employed for twenty minutes.

The above is the ante-mortem history as given by my acting house physician, Dr. Taylor. On entering on duty on the 1st of March I found the patient with evidences of pyo-pneumothorax, the air having been found in the chest after an aspiration, and at that time evidence by amphoric respiration, voice, and cough of a communication of the pleural cavity with the bronchi. Of this part I had satisfied myself on the day after the aspiration. No evidence existed of such communication on the 1st of March, as there was absence of respiratory murmur of any kind and of the amphoric voice over the air in the chest. Dr. Peck, the house physician, assured me that no pus had been coughed up. I supposed that the cause of the entrance of air after the aspiration had been due to a small perforation of lung in some spot where perhaps the pleura was thinned by ulceration, or possibly at

the site of some abscess which had caused the empyema. The doctor assured me that he had not felt anything like the lung impinging on the needle during the aspiration. There were no evidences of disease in the other lung, save occasional râles, and this I ascribed to a slight bronchial catarrh, though I heard them at the apex. I weighed the case in my mind and decided in favor of opening the thorax for the following reasons:

1st. The previous aspiration had not reduced the size of the pleural cavity.

2d. The pus had reaccumulated.

3d. The lung, owing to the air and pus, was collapsed and pressed inwards and backwards on its root, and no signs existed of present communication between lung and cavity.

4th. The results of the operation in other cases had been favorable, either curing or alleviating to a greater extent than repeated aspiration.

5th. I had seen a number of cases in which death had occurred where the operation was not performed, and I believed and believe that a greater number will recover of those operated on than of those not operated on.

6th. I did not see any good reason to hope for a diminution of the pus-producing cavity except by opening the chest and allowing the pus to escape, and then endeavoring to obtain a retraction of the affected side.

I stated at my clinic that I would have much preferred operating on the case had the upper lobe been adherent to the chest wall, as it so often is in empyema, thus reducing the size of the pus-producing cavity.

*Autopsy twenty-seven hours after death.*—Brain normal. On opening the pericardium I noticed that the right ventricle was distended, and hence percussed over it. It was tympanitic. I then punctured it with the point of a knife, and a quantity of odorless gas or air escaped with a "piff" sound, and the walls fell together. There was also some air in the right auricle. I immediately examined the condition of the vena cavae, and found no lesion of them nor of the innominate veins, etc. The right ventricle contained, after the air escaped, only a few small clots not in the least different from ordinary black clots; the right auricle some black clots and fluid blood. The left ventricle was nearly empty and contained no gas, the left auricle contained only blood.

I have to regret that in the examination I could not speak of the contents of the pulmonary artery with certainty, as the heart was cut out, and I think blood seaped. In the left lung the branches contained blood. In the right the branches, when I removed lung, were nearly empty.

The right pleural sac contained some of the remains of the fluid injected, and the rest was filled with air. The right lung was collapsed, carnified, pressed upwards and inwards on the root. The pleura covering it was thickened and opaque, and presented at the upper part of the lower lobe an irregularly oval loss of substance about an inch long and one-half an inch in depth leading into the lung tissue. In this I found a branch of the pulmonary artery of some size separated from the air-holding space of the pleura only by the thickness of its own walls. The costal pleura was markedly thickened. The other lung was normal. The liver and kidneys were somewhat congested, but otherwise normal.

There were evidences of old pelvic cellulitis and crinitis, and of some thinning of uterine wall at point of flexure junction of neck and body.

The other viscera were normal. A careful examina-

tion showed absence of gas development in the blood; in other situations an absence of the least sign of decomposition about the body or its organs, and you see in the lungs and heart which I present after two days the absence of any evidence of decomposition at the present time, these organs having been preserved simply by exposure in the atmosphere wrapped in a damp cloth.

I had supposed that the evidence as to the cause of the sudden death would be negative, and that we should have to consider it as due to syncope; but finding the gas in the right side of the heart without evidence of decomposition as its cause, and finding it there exerting pressure on the containing wall, it seems to me that we shall have to consider it as the cause of the arrest of cardiac action. The question arises as to its origin. It could only come from the vena cavae, the vena azygos, or the pulmonary artery on the right side, or else be developed from the venous blood. I looked at the vena cavae and the vena azygos, and there was no point for its entrance in these, and in the azygos there was fluid blood without air bubbles, so that it did not pass from an intercostal vein into this. If the pulmonary artery alluded to had been its source, we should expect evidence of blood escape into the tissues if a lesion existed in its walls; and more, the air would, in case of no lesion, have made its way in opposition to blood current, and through the valves. I had at first thought of this as a possibility, but I must confess that more mature reflection makes me feel that it is a scarcely probable case.

The other supposition which I have mentioned, viz., the development of gas from the blood, I believe to have been the real condition and cause. This, as a cause of sudden death, is spoken of by Foerster, though he says he never saw a case under the head of pneumatosis of the heart, in his work on pathological anatomy. He also there gives some literature citations. Rokitansky and others, as far as I have had time to examine them since, pass the subject without mention, or as Wagner with the barest allusion.

Some years since I saw a case of gangrene of the leg due to a diffuse cellulitis, in which the death was very sudden, and in which I supposed that gas had entered the circulation from the decomposed blood in the veins of the affected part, as I found it there in the right cardiac cavities; but as the weather was warm and the body commencing to decompose, I could not be positive.

This and the case I present to-night are the only cases of the kind in my experience. I record the case on account of its rarity, and also because I believe that we should report our unsuccessful as well as our successful cases.

#### CEREBRO-SPINAL MENINGITIS—PSEUDO-MEMBRANOUS CROUP.

Dr. M. P. Jaconi presented the larynx, right lung, and the spinal cord from a babe five months old. She saw the patient only once, and that half an hour before its death. Two weeks before this, the patient, together with another child, aged twenty months, and of the same family, was seized with vomiting and fever; showed evidence of pain in the head and rigidity of the sterno-cleido muscles. The pulse, at first rapid, soon became slow and intermittent. There was only a single attack of vomiting; no other sign of gastro-intestinal disturbance, nor of lesion of any other apparatus than the nervous. In the older child there was a diffused erythematous redness over the body, which lasted one day. The other symptoms lasted five days, and gradually disappeared. Then

both children were seized with catarrhal fever, ushered in by stomatitis, attended by some degree of laryngitis and intense bronchitis. The symptoms of the first week seemed of more importance from the fact that, four weeks before the children were attacked, the mother had been seized with precisely the same symptoms, with the addition of vertigo, which still continued. The pain in the back of the head and neck had been intense, and accompanied by cutaneous hyperaesthesia. There had been also suffusion of the eyes, carache, and some dysphagia. In her case there was but little fever; but she still kept her bed, six weeks after her seizure.

The babe, after passing through its catarrhal fever, was apparently recovering, when one night it suddenly fell into a condition which the two physicians who saw it described as resembling an apoplexy or the effects of an overdose of opium. It was insensible, and incompletely paralyzed; the respiration at first little interfered with, although some hoarseness existed. Soon, however, the supra-clavicular spaces began to be depressed, as also the epigastric region during inspiration. There was no decided stridor of croup, but simply a noisy sound at inspiration. When Dr. Jacobi saw the child it was completely cyanosed, and evidently suffering from marked laryngeal stenosis. Auscultation was then quite unsatisfactory, and dullness was discovered at the base of the right lung. Death occurred ten hours after the seizure. The opinion was expressed by Dr. Jacobi that the first attack of illness was an abortive form of cerebro-spinal meningitis, such as is described by Hirsch. The death, however, was evidently due to asphyxia—in all probability from membranous croup, suddenly developed upon the catarrhal laryngitis.

The autopsy was made seven hours after death. The brain presented all the appearances of asphyxia; otherwise was normal. The spinal cord was hyperaemic. A soft black clot, half an inch in length, was discovered lying under the pia mater, on the right antero-lateral column of the cord in the cervical region. A pseudo-membrane was firmly attached to the entire mucous surface of the larynx, whose mucous membrane was hyperaemic, but not eroded. A mucopurulent secretion occupied the trachea and right bronchus, while the portion of lung corresponding to the latter was solidified.

The points of interest in the case were: 1st. The very rapid development of the pseudo-membranous croup, and the absence of diphtheria. 2d. The collapse of the entire lower lobe of the right lung, apparently in consequence of the obstruction of the bronchus. The question arose whether this collapse had taken place gradually, or had occurred suddenly, and so marked the invasion of the acute fatal symptoms. 3d. Another question, whether the clot in the cervical cord indicated a hemorrhage that had occurred at the outset—therefore in a morbid cord—or was merely the consequence of the asphyxia. 4th. Finally, the cerebro-spinal symptoms during the first half of the illness, which, from the clinical grouping, suggested the diagnosis of an abortive cerebro-spinal meningitis.

After the presentation of a specimen of Bright's kidney by Dr. Messenger, the Society went into executive session.

TRAINING-SCHOOL FOR NURSES.—The building formerly occupied by the Medical Department of the University of this city, has been purchased for the Training-School for Nurses, is being fitted up for early occupancy.

### CHEAP MEDICAL EDUCATION.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—I thank you for your article on the subject of Cheap Medical Education; but desire to take exception to it in one or two instances, where I think you have a wrong apprehension of the other side of the question.

You take a very practical, business-like view of the matter, but you will certainly have to admit before you are through, that merchandise is not medicine, and that you cannot even compare them in the matter of medical instruction and its recompense, and still hold to the long-established imputation of honor in the profession. Our western professors will hardly thank you for your microscopical idea of their consciences in the matter of imparting instruction to students.

If it is a case of so much education for so much money, then I apprehend few would be slow to acknowledge the fact; if they do not, a stigma is cast upon the pretensions of those who have such institutions in hand, and their business must be illegitimate; and yet I dare say no professor of any branch of medicine, outside of New York, would say that the instruction he gives is not the very best he can, regardless of price. How, then, can you harmonize professional honor with this conscienceless business; for it is nothing less, since there is no responsibility greater than that which rests upon those whose business it is to impart a knowledge of medicine to those who intend to make its practice the business of their lives. I am acquainted, personally, with but one medical faculty; but I opine *they* are not composed of the cheap sort of stuff you so flippantly refer to. You seem to forget, in speaking of the large number of students who are willing to pay the high prices for instruction, that there is a disposition in the average American youth to excel, and that oftener in the case of spending his dollars than in that of acquiring knowledge, and I am of the opinion (perhaps wrongly so) that the *prestige* gained by attending Bellevue or the University, would weigh more in the balances against the cheaper school, than a conviction that the *knowledge* to be gotten is superior. One does not seldom find proof of this, even as far west as Wisconsin, in the stragglers from the "Metropolitan" schools that are occasionally met with. It would be only boasting to attempt to refute the slur that is cast upon our western practitioners in asserting that they cannot compete with their brethren of Boston, Philadelphia, or New York; so I pass it. I quite concur with you in the fact that cities which do not furnish sufficient clinical instruction are not the ones desirable for medical colleges; but cities the size of Chicago and Cincinnati furnish an abundance of clinical material, and it is somewhat amusing, to say the least, to see them classed among the "obscure towns." Your argument as to "scanty means" and "scanty time," and the poor chances of professional success, which you say necessarily follow these, is not valid, as you and every one else have every opportunity for knowing; for we meet daily, in print and out, with those whose circumstances have been those you describe who have attained to affluence, and many to eminence by the exercise of that medical judgment which had its training in the cheap schools of the country.

In looking over the names which stand at the head

of the profession in America, we find not a few whose early medical career was not promising, by reason of scanty means.

Among those names is that of Prof. N. S. Davis, of Chicago, one of the founders of the American Medical Association, and who is at present Dean of one of those cheap colleges of Chicago.

J. B. STAIR, M.D.

JUDA, WISCONSIN, April 2, 1877.

## MEDICATED DISCS FOR HYPODERMIC INJECTIONS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Every once in a while we find in the *Lancet*, *Medical Times and Gazette*, and other English journals, puffs of various proprietary articles. Recently, Savory & Moore's medicated gelatine discs, for making hypodermic injections, received a flattering notice.

To-day we obtained a small package of them marked morphia gr.  $\frac{1}{6}$ . In the package were twenty-two discs, the total weight of which was less than two grains, or less than a tenth of a grain each. Query: How can S. & M. put a sixth of a grain of morphine into a wafer, which, including gelatine and medicine, weighs less than the tenth of a grain?

Respectfully yours, H. G. P.

## THE NEW YORK HOSPITAL AND SMALL FEES.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—The profession is under many obligations to the RECORD for the outspoken manner in which it criticises medical abuses, and if any fault is to be found in regard to the article on the New York Hospital management, it is that not sufficient severity has been used. In a recent number of the *New York Herald* the regulations of the out-door service of the New York Hospital are published, and from them it would seem that the institution assumes to itself the rôle of consulting physician and surgeon, and proposes to furnish the patient with a written opinion for the guidance of the regular medical attendant (regulation ninth). I would wish to inquire if such a proposition is not opposed to the sentiment of the profession, and a dishonest assumption of the rights and prestige of an hospital over those of the ordinary attendant; for what physician would care to be presented with instructions from the out-door department of any hospital regardless of the position such an hospital might hold?

JUNIUS.

NEW YORK, April 7.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—The editorial in your issue of April 7th, on "The New York Hospital and the Abuse of Medical Charity," will certainly receive the hearty endorsement of the great mass of the profession in this city and neighborhood. There is one point, however, to which you did not call attention, namely, that the rapid medical service scheme inaugurated by the governors of the Hospital, to be successful, requires the acquiescence and co-operation of the attending physicians and surgeons. In other words, they become parties to the matter. Now, most of these gentlemen are eminent in the profession, and enjoy fair, and some

of them large, professional incomes, a portion of which are derived from patients, medical, surgical, and special, that have been referred to them by, in many instances, their less prosperous brethren. Now, with unseemly ingratitude, not content with that which has been freely given to them, they make a special effort to deprive the humbler members of the profession of even the little that is left to them, fulfilling the old proverb, "To him that hath shall be given, and from him that hath not shall be taken away even that which he hath." The Clinton Medical Institute, the New York Medical University of J. Walter Scott, *et id genus omne*, which charges, I believe, \$10 per month, or so, for medical services, are in these particulars respectable in comparison with the New York Hospital. If the attending physicians, surgeons, and specialists of the Hospital continue to participate in this arrangement, the rest of the profession must, I presume, submit and suffer, unless, by withdrawing the consultation practice which they have heretofore thrown in their way, they finally succeed in bringing these gentlemen to a proper sense of their duties to their younger and less prosperous brethren. The hint that I here throw out I shall personally act upon, and I recommend its consideration to all who feel aggrieved by the action of the New York Hospital.

Respectfully yours,

A STRUGGLING PRACTITIONER  
OF TEN YEARS' STANDING.

JERSEY CITY, N. J., April 7, 1877.

## DANGER OF INTRODUCING FLUIDS INTO THE NASAL PASSAGES.

TO THE EDITOR OF THE MEDICAL RECORD.

MY DEAR SIR:—Having this moment laid down No. 333 *Medical Record*, March 24, 1877, in which "The Danger attending the Introduction of Fluids into the Nasal Passages" is considered, I hasten to say, that in a general practice of fifteen years, I never remember to have seen a patient who employed medicated fluids in the fashion referred to, but that sooner or later was obliged to desist through discomfort or mischief to the ear.

I not only approve, but for some time back have worked on the plan suggested by Dr. Buck—swabbing out the naso-pharyngeal tract.

GEORGE H. MITCHELL, M.D.

23 FRANKFORT STREET.

## AN EXTRAORDINARY CASE OF OPIUM INEBRIETY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—I have recently visited a most remarkable man, whose eventful life presents so many interesting features that I think a short sketch will be acceptable.

Capt. Frederick Labrbush was born in London, March 9, 1766, being now more than 111 years of age. This fact is well authenticated. Entering the British service at twenty-three, he was promoted for gallant action to a captaincy, and in that capacity served in various countries—Spain, Holland, India, and elsewhere, being part of the guard over Napoleon at St. Helena until 1818, when he left the ranks and became Governor of a convict station in Australia. In 1824, on a voyage to England, he was shipwrecked, losing his wife and all his earnings—£15,000 gold—and was himself picked up, senseless and exhausted. After twenty-four years more of this roving life he settled in New York, where he has since resided.

The principal point of professional interest in this history is, that Capt. L. has been an opium habituate for seventy years! A statement so extraordinary may seem incredible, but it is well attested. In 1807, while in India, he was attacked with diarrhoea, which gave way only to opium, and, when the legitimate necessity for its use had been fulfilled, he found himself, as is so often the case, an inebriate.

Taken, at the outset, in small doses—half-grain at most—and occasionally only, no increase was made for two years, and up to the tenth the additions were limited. From that to the fourteenth he advanced from twenty to thirty-six grains. From this point there was progressive increase, finally reaching a maximum of *ninety grains per diem* in 1856, when he came into the care of a gentleman who has since been his medical attendant. By judicious management this inordinate amount was gradually decreased, until in 1853 his quantum was only a half-drachm daily. Still further reductions were practised, and, for the last five years the dose per diem has been but a four-grain pill at bed-time. Proof as to this reduced amount is given by the fact that during its taking he once, in a fit of pique, swallowed six pills at a dose, and was thoroughly narcotized, which would not have occurred had he been habituated to a larger quantity.

Alvine torpor has been constant, causing at times a marked tumor in the ascending colon often so painful as to demand professional interference. The ordinary obstipation has been met by enemas. Forty-eight hours is the maximum abstinence, any excess in this direction being invariably followed by diarrhoea and profound malaise. No other ill results of special import have been noted, and, till the middle of January, his health had remained sufficiently good to admit of passing several hours daily out of doors.

At the time of my visit—March 31—he was confined to bed, very feeble, and his early demise expected. Ten weeks before, after returning from a social call—made in a cab, several blocks distant—he was seized with a severe chill, resulting in marked pulmonary congestion with alarming symptoms, and, although he rallied very unexpectedly from the acute stage, it has been followed by such prostration as to make his recovery well-nigh impossible.

This case is certainly unique; medical literature, so far as I know, furnishing no parallel. Somewhat approximate instances may be found in Christison's work on Poisons, the maximum habituation reaching fifty years.

No less notable is the absence of the usual disastrous sequelae of opium addiction. For this it is difficult fully to account. He is, undoubtedly, a physiological anomaly. His habits too, have been very methodical—among others, retiring at 5 P.M., and rising at 1 A.M.—and to his exactness in this and others must be largely attributed his five score and eleven, with such unusual freedom from physical ills. Much, also, has been due to the judicious care of his medical adviser in reducing his great consumption of opium to an amount sufficient for his actual need, and, with attention in other regards, thus obviating almost entirely the ordinary results of opiate excess. But, with all that can be advanced, the case stands alone and inexplicable.

I am indebted to Dr. Thos. C. Chalmers—for the last twenty-one years Capt. L.'s physician—whose courtesy I wish to acknowledge, for many of the facts in this paper.

J. B. MATTISON, M.D.

BROOKLYN, N. Y.

## ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from April 1 to 7, 1877.*

JESSOP, S. S., Ass't Surgeon. Assigned to duty at Edgefield, S. C. S. O. 64, Dept. of the South, April 5, 1877.

AZPELL, THOS. F., Ass't Surgeon. Relieved from duty at Fort Columbus, N. Y. H. S. O. 69, A. G. O., April 2, 1877.

MOFFATT, P., Ass't Surgeon. Assigned to duty at Fort Foote, Md. S. O. 74, Division of the Atlantic, April 3, 1877.

TURRILL, H. S., Ass't Surgeon. Granted leave of absence for one month, with permission to leave limits of the Department and apply for an extension of three months. S. O. 60, Dept. of Texas, March 30, 1877.

COLLEGE OF PHYSICIANS AND SURGEONS, N. Y.—The *University Herald*, Syracuse, N. Y., charges the Faculty of this institution with graduating, at the last commencement, a student who is not twenty years of age, who studied medicine but two years, and who has not attended two full courses of lectures. The said graduate is charged with affixing "A.B." to his name without having received a diploma therefor. If the Faculty care to know the name of this enterprising gentleman we shall be happy to furnish it, with such facts as have come in our possession.

NEW YORK ACADEMY OF MEDICINE.—At a stated meeting of the New York Academy of Medicine, held April 5, 1877, Dr. George H. Butler and J. P. P. White were elected resident Fellows.

DR. JAMES R. WOOD has been appointed consulting surgeon to the New York City Lunatic Asylum, Blackwell's Island, and New York City Asylum for the Insane, Ward's Island.

BEST TIME TO DRESS FRACTURES.—Prof. Yandell in a lecture to his class, answers the question as to the best time to dress a fracture, thus: "*The earliest possible moment after the bone is broken.*" This is common sense; and the idea that people, and often inexperienced doctors, have of removing the patient from the place of accident to his home or other point, before dressing the fracture, is fraught with great risk and injury to fractured limbs. Dress it on the spot, even if you have to go miles in search of material to do it with.—*Southern Medical Record.*

## Original Communications.

## A NEW OSTEOCLAST, WITH REPORT OF CASES.

REMARKS MADE BEFORE THE N. Y. ACADEMY OF MEDICINE.  
APRIL 5, 1877.

By C. FAYETTE TAYLOR, M.D.

On the fourteenth day of February, 1866, while crowding forcibly but steadily upon the thigh of a patient for the purpose of correcting a serious deformity at the left hip-joint, I felt a sudden giving-way, and with a dull thud the limb dropped upon the operating-table. I had fractured the femur in its upper third. I immediately remarked to Dr. E. R. Peaslee, who was holding the pelvis, that I hailed the accident as a special good fortune. A modified Davis-extension splint, with hip-band and two perineal straps, was at once applied, and just sufficient extension made to prevent any overlapping of the fractured ends of the bone. Rotation of the leg was prevented by a piece of wood attached to the bottom of the splint. A piece of gutta-percha was moulded to the under side of the thigh in such manner as to prevent the distal and proximal ends of the bone, at the point of fracture, from being separated. No change whatever was made in the dressing during the next six weeks. At the end of that time, although a firm callus had rapidly formed, it was advised that the patient continue to use crutches for several weeks longer. The patient immediately sailed for Europe, and while on shipboard attempted to use the limb, but found that it was not quite firm at the seat of fracture. On reaching Paris, M. Nélaton was consulted, who discovered motion, and had constructed a suitable apparatus, which the patient wore two months. Soon, however, the limb was used with perfect facility, and with an almost complete correction of the deformity. Subsequent examination proved that there was motion at the hip-joint. Since the occurrence of the events related above, I have been looking for an opportunity to test my conviction that in fracture of the femur we have the simplest and most practical means for ameliorating the condition often presented when disease of the hip-joint has terminated with the head of the bone fixed in the socket and the femur in a distorted and irreducible position.

As opposed to section, which is producing a compound fracture, it seemed to me there were evident and decided advantages in favor of a simple fracture. The one thing lacking was some simple and reliable means for producing fracture *at the elected point*. I have never doubted, since the experience in the case related, that with a suitable osteoclast, and sufficient experience to test its merits, fracture will take the place of section of the bone, and be employed in cases in which there is such depraved constitution as renders section completely out of the question. I have suggested the operation in many cases, but with only the accidental experience I had had in a single instance could not urge it with sufficient confidence to induce any one to submit to the procedure. At last a case presented itself, in which the patient was so utterly helpless, and his condition so desperate, I had but little difficulty in persuading him that his only hope was in the operation which I am advocating.

Oscar Field, *et. sixteen years*, in December, 1873, presented himself in the following condition: His right thigh was abducted to the fullest possible extent, flexed at a right angle with the pelvis, and fixed

in that position by a firm ankylosis, which had occurred at the hip-joint as the result of morbus coxarius. (See Fig. 1.) There was caries of the left tarsus, with

FIG. 1.

several sinuses presenting a sluggish appearance, and marked cachexia. He had been sitting in a chair most of the time for two years, because of his utter inability to move or to be moved. On account of shortening of the hamstring muscles the leg was flexed to a right angle with the thigh, and there was but trifling motion at the knee-joint. The case, although unpromising, was, as I thought, not without hope. The first step in the treatment was to give the patient a little exercise, and afford him an opportunity to breathe the fresh air. Suitable apparatus was adjusted and from the trifling exercise he was enabled to take and the fresh air his general condition rapidly improved. At the end of about one year the last tarsal sinus had healed, but there was ankylosis between all the tarsal bones. Although improved in health, and having the ability to support himself upon one foot, yet as he could not balance upon it, owing to the want of motion in that ankle, he was practically as helpless as before. I urged the operation of fracturing of the femur as being one especially applicable to his case. I regarded the case as too strumous to make section justifiable if a simpler method of treatment could be found. The plan was accepted by the patient and endorsed by Dr. George A. Peters, who rendered valuable assistance, and accepted a share of the responsibility. The osteoclast as used is now presented (see Fig. 2), and consists of a U-shaped bar of iron (A B), three-fourths

of an inch square, on one ramus of which is placed a hard-rubber pad one-and-three-fourths inches wide, and curved to fit the rounded surface of the thigh. On the side opposite to this pad a V-shaped bar of iron (C) is fitted under the ramus, and controlled by two screws (D D), which pass through the ramus itself.

FIG. 2.

A strong piece of hard wood is used for the fracturing lever (E F). At the lower end of the lever a pad (G), similar to the one just described, is firmly fastened, and is intended to rest over the trochanter major. The pad resting over the trochanter major, the body of the lever passes under the V-shaped piece, extends along the femur and parallel to it, and has fitted into it at the distal extremity female portions of a screw, through which a threaded rod works as it rests in a socket (M), upon the outer side of a free pad (K L), also rubber-lined, that is placed in contact with the distal extremity of the femur. The threaded rod terminates in a crank-like handle, S R, P. The instrument was applied diagonally pointing towards the left shoulder. By this expedient the important vessels and the larger portion of the muscles of the thigh were excluded from the possibility of receiving injurious pressure. The regulating screws (D D) were then adjusted until the three pads, A, K L, and G, sustained a uniform and firm pressure, and by a few rapid turns of the handle S R, P, the distal pad, K L, was driven forcibly against the thigh, when, with a sharp report, the fracture was produced at the point selected, namely, beneath the pad at A. The selected point was as close to the pelvis as the apparatus could be adjusted; in reality in the upper third of the femur. Considerable force was required to produce the fracture, but it is a remarkable fact that no perceptible impression was made upon the soft parts, evidenced either by discoloration or tenderness upon pressure over the parts where the pads were in contact with the surface of the thigh. I also find that Rizzoli states that no bruising of the soft parts occurred in his cases. In consideration of the acuteness of the

angle at which it would be necessary to place the ends of the fractured bone, and the increased liability, as I apprehended, of shortening, I had a splint constructed which was intended to meet as many of the apprehended difficulties as possible. It provided for securing the exact position desired, and also provided against displacement by muscular action, an extension splint being part of the apparatus. The splint was applied, and, with the exception of that caused by the anæsthetic, no pain or distress was experienced during the entire period of his confinement. Although the patient ate and slept well, and had no unfavorable symptoms, it was found that union did not take place rapidly, for on the fiftieth day motion was readily recognized at the seat of fracture. It was then de

FIG. 3.

ecided to remove the splint and apply a plaster-of-Paris dressing in order to give the patient more freedom, in the hope that moving about, even though but slightly, might facilitate union.

Having been suddenly attacked with a severe illness on the morning appointed for the substitution of the plaster-of-Paris for the original dressing, the change was most skilfully made by Dr. Peters, assisted by Drs. McBurney and Chrystie. After the application of the plaster dressing, which extended to the waist

and [closely invested the pelvis, the patient was able to sit up, and when, on the first of March, 1876, the bandage was opened, and the fracture examined, it was found that considerable progress had been made towards complete reparation. Although there was motion at the point of fracture, the ends of the bone were held sufficiently firm in position to prevent any displacement, and the patient was permitted to return to his home in the country, still wearing the bandage. He returned for examination on the first of April, when it was found that a good callus had been formed, and there was some doubt whether there was any motion at the point of fracture. It was decided, however, after careful examination, that very slight motion still remained. The dressing was readjusted, and on the 23d of May there was no longer any doubt regarding the solidity of the union, and the bandage was removed (see Fig. 3).

FIG. 4.

Six years had passed since the patient had been able to walk, and, as had been apprehended, he was still unable to walk, because of the atrophy of the muscles and contraction that had taken place. These were gradually overcome by appropriate exercise, and he is now able to walk with perfect ease (see Fig. 4). As

will be noted it required something like five months for solid union of the bone to take place, but, considering the highly strumous condition of the patient, this delay in reparative process ought to be an argument in favor of fracture as a means for correcting excessive deformity with true ankylosis, when compared with the probable result after section in the same case. Be the advantages with the one or the other operation in this class of cases, so far as exemption from dangerous consequences may be concerned, there can be but one conclusion, I believe, in comparing such a result as was obtained in this case with any artificial joint which was ever formed. Except free motion in a sound joint, there cannot be so good a result as ankylosis when the femur is in a selected position. Such selected position would be with the thigh slightly flexed upon the pelvis, and the limb parallel with the longitudinal axis of the body. In such a position the centre of gravity is placed directly over the base, with but a slight and scarcely observable motion of the trunk in walking. Altogether there is but a slight disability in such a case. There is, of course, increased motion in the lumbar vertebra, but it is divided about equally between the act of lifting and straightening the limb, consequently is not conspicuous, and the motion for both steps takes place in the unaffected hip-joint.

The length of time required to secure perfect union in these cases should not be surprising. Unquestionably, when an angle is made at the point of fracture, there cannot be so large surfaces in contact as when the fractured ends of the bone are kept in contact by overlapping or direct apposition, as in oblique and transverse fractures. Besides, there is a much larger space to be filled with osseous material between the portions of the bone which are not in contact, so that it would seem reasonable to expect a considerable prolongation of the time usually required to repair an ordinary fracture which is set in a straight line. I do not perceive, however, that this fact alone should be a serious objection to the substitution of fracture for section as a means for correcting a serious and irreducible distortion at the hip-joint, especially if it is found, as in the case reported, that the ultimate reparation is as perfect as obtained in ordinary fractures.

With regard to the kind of splint to be used in such a case, my first impression was, after the plaster-of-Paris dressing had been applied, and apparently with so much benefit, that it might as well have been used immediately after the fracture had been produced; but having since seen several serious results in cases in which plaster-of-Paris has been employed in the treatment of ordinary fractures, I shall again begin the treatment after the fracture with an apparatus similar to the one before employed. Indeed, I do not now see how the management of the case related could be well improved, and therefore shall go over the same ground in the treatment of subsequent cases until experience has indicated that some change should be made. I believe that the results in the cases reported recommend fracture of the bone in preference to section as a means for correcting deformity, especially as the osteoclast so perfectly fulfils the purpose for which it was designed—namely, *to enable the surgeon to produce a transverse fracture at any selected point with ease, certainty, and safety from after-complications.*

There is nothing new in the idea of refracturing bones for the purpose of correcting deformity.

Without going over the literature of the subject, I will call attention to the labors of Rizzoli, an Italian surgeon, who had his attention first called to the use of an osteoclast in 1845. His object was to secure an

oblique fracture, and he constructed an osteoclast with that object in view. It is evident that with an oblique fracture, lapping of the fractured ends can be much more satisfactorily accomplished than when the fracture is transverse. On the other hand, my object has been to produce a transverse fracture for the purpose of bringing the fractured ends together at a more or less obtuse angle, thus completely changing the direction of the limb. Consequently, the means for producing the fracture should be somewhat different. Each instrument seems to answer the purpose for which it was devised, but one could not be substituted for the other, especially as Rizzoli's fractures were made in the middle of the femur, while my special desire, besides securing a transverse fracture, has been that it should be at a point nearest possible to the hip-joint. Rizzoli's conclusions are very important. He says there was no bruising of the soft parts by the osteoclast. As he generally used it without anæsthetics, his testimony should be conclusive that the fracture was produced without pain. In no case does he report any constitutional disturbance in consequence of the operation. It must be remembered, however, that Rizzoli always fractured the sound limb. He relates several cases of shortening in consequence of luxation of the femur, but as in shortening from fracture it was the unaffected thigh which was subjected to the osteoclast's embrace. He gives no case at all similar to those which I have related—and so far as I have been able to discover, these are the first instances in which the same or like procedure has been adopted—namely, fracturing the femur at its upper third, and making a small but unimportant deformity at that portion of the bone for the purpose of overcoming the malposition of the whole limb, in connection with ankylosis at the hip-joint.

### VASELINE AND SALICYLIC ACID IN MEDICINE.

By HENRY A. DuBOIS, M.D.,

SAN RAFAEL, CAL.

In two former brief papers in this journal I have noticed some of the uses of vaseline and salicylic acid, alone or combined, as an ointment in the treatment of wounds and in obstetrics; in the present I will make some suggestions as to their use in another class of cases. Ulcerations of the septum of the nose are often as much the cause of persistent discharge from the nostrils as erosions of the os uteri are the cause of leucorrhœa. I have seen many cases that, under the care of specialists, have, for the time being, been cured, only to break out afresh. In truth, these cases seem to require general as well as local treatment. Looked at from one standpoint, they are but a sign of a general constitutional state. The treatment pursued by most specialists is tedious, requiring the attendance of the patient several times a week for several months before the ulcerations are completely healed and the discharge stopped.

Many of the cases that come to the general practitioner would be satisfied if they could get a partial cure, *i. e.*, be able to control the discharge from the nostrils to such an extent as not to be seriously inconvenienced thereby. It is a question in some of these cases as to the advisability of stopping suddenly a long-continued discharge. The treatment that I have found most convenient for the patient, and at the same time very effective locally, has been the use, night and morning, of vaseline with five grains of salicylic acid added to the ounce. This is

introduced into the affected nostril by a camel's-hair pencil, or better still by a little cotton-wool wound around the end of a stick. At the same time I give  $\frac{1}{100}$  to  $\frac{1}{50}$  grain of corrosive sublimate with some preparation of iron twice daily. I frequently find that after this treatment has been continued for one to two months a complete cure is effected, while in other cases the discharge has so far ceased after a few weeks that the patient, being satisfied, leaves off the treatment. In cases of scrofulous enlargements of the glands of the neck, vasoline, with from ten to twenty grains of iodine and the same quantity of iodide of potassium, makes an excellent ointment. In hemorrhoids vaseline with five to ten gtt. of tar to the ounce, makes a very soothing application to the inflamed piles. Ten to twenty grains of subnitrate of bismuth may be substituted in some cases for the tar, with advantage; of course the portal circulation must at the same time be kept unobstructed. In granular lids, vaseline alone introduced into the eye soothes the parts, and has given good results in my hands. If desired, alum, sulphate of zinc, or, what I prefer, liq. ferri persulphatis, can be added. I believe that vaseline containing one-half to three grains of salicylic acid will be found useful in purulent ophthalmia. Indeed, the use of these agents in diseases of the eye has received, so far, little attention. In otorrhœa in scrofulous children, the vaseline, with varying proportions of salicylic acid, checks the discharge and relieves all excoriations caused by it. In granular sore throat the ointment, if applied morning and night with a probang, answers a good purpose, and I may add that in diphtheria I prefer to apply the acid with vasoline rather than in solution. Vaseline in many skin eruptions soothes and protects from the air. Recently I have had charge of a case of small-pox in a child, in which I kept the ointment constantly applied to the whole body, with the effect of apparently entirely relieving the itching; for the child, though of a very irritable disposition, did not break a single pustule on the face by scratching, and recovered without a pit. I should also mention that the secondary fever was almost absent. I do not think I am going too far in saying, that a daily application of this ointment, in cases of small-pox, over the whole body, will not only greatly conduce to the comfort of the patient, but will do much towards reducing the fever of maturation. In cases of poison-oak, I find it to give more relief than any other topical application, and, in connection with vapor or hot-air baths, to effect speedy cures. In cases of burns it answers much better than caron oil. The ointment stimulates the granulations, and by the addition of astringents, will furnish a good dressing throughout all of the stages of an extensive burn. It answers well as a dressing for chancroids. In cases of baldness or loss of hair after fevers, vaseline with twenty grains of quinine and thirty gtt. of tincture cantharides makes an excellent pomatum. It takes, in many cases, the place of liniments, and can be combined with quite a variety of active medicines. It may be used instead of cod-liver oil as an external application in diseases of mal-assimilation, and will not be found disgusting like the former, while it seems to have nearly if not quite as good an effect on the disease. I have used it internally in phthisis, chronic bronchitis, and whooping-cough, and with generally satisfactory results; but the consideration of its action when used internally must be postponed until my experience is more extensive than at present.

I will conclude by mentioning a number of little uses in which vaseline will be found to contribute to

the comfort of the patient and to the convenience of the physician. It makes a good dressing for blisters, and a more soothing one than any other with which I am acquainted. Added to poultices, it keeps them moist, and, if a little of the acid is added, sweet for a length of time. It is a good vehicle for active medicines when used by the rectum. The vaseline should be slightly warmed, and the nozzle of the syringe large. If introduced in the melted state into the urethra, in cases of difficult strictures, it enables the catheter to enter with great facility. It answers better than mercurial ointment to prevent rust on instruments. I have no experience in its use in gonorrhoea, but I think there can be little doubt that with its soothing and penetrating qualities, it would make a good agent for astringents, and with the salicylic acid would tend to abate inflammation and check the discharge. The ointment alone or with tannic acid is a valuable application to bed-sores. I may add that on blistered feet, and for the sore backs of horses, it answers well. I have thus briefly called attention to these agents. No doubt most physicians have used them in many cases; but so far as I know all of the valuable properties of vaseline, alone or combined with salicylic acid and with other active agents, are not yet fully appreciated by the profession generally, and this must be my excuse for mentioning many of the uses that these agents may be put to.

### BELLEVUE HOSPITAL.

#### NOTES OF PRACTICE AND PECULIARITIES OF TREATMENT.

CASES OF SYPHILIS—PREMATURE AGE—INTERESTING HISTORY—DIAGNOSTIC POINTS BETWEEN SYPHILITIC TUBERCLES AND LUPUS—TEST BY TREATMENT—CURIOUS FACT REGARDING IODIDE OF POTASSIUM—INFANTILE SYPHILIS—APPARENT ABSENCE OF SYPHILIS IN THE MOTHER—CONSIDERATIONS ON THE CASES.

Three cases of syphilitic disease were presented, each of which exhibited peculiarities worthy of note. The first case was a very good illustration of *premature age*, produced by syphilis, and was regarded as rather characteristic of the malady. The patient looked to be so much as sixty years of age, but she distinctly stated that she was no older than forty-five years. Sixteen years ago she first had an eruption upon her nose, and cicatrices were remaining. Two years ago little pots were occasionally seen upon the chin; but during the last eight months the disease had appeared upon the chin, had existed continually, and had gradually extended until it involved all the skin of the chin and lower lip.

There was no eruption upon any other part of the body, but she had suffered severely from rheumatism, both of the joints and shafts of the bones. It was thought not improbable but that she may have had ordinary articular rheumatism, together with a syphilitic rheumatism affecting the shafts of the bones. It was believed to be rather common for gout and syphilis to occur in the same individual, and for each disease to present its peculiar characteristics at the same time. The same might be true of rheumatism.

With regard to the causation, it was found that there was a history of four still-births. That fact had

an important bearing upon the existence of specific disease in the woman. Her husband, she said, died of heart disease, and in his last sickness had "seven doctors to him," which was a serious complication. He also had a sore upon his foot, which lasted for two years, a fact which, taken in connection with the statement that he was the father of four children who died in utero or at birth, made the presumption fair that the chronic sore upon his foot was an ulcerating syphilitic.

It was suggested that we had to deal with another disease rather than syphilis, for the eruption presented some of the features of lupus. Why should it not be regarded as a case of lupus? All the elements of the history had a certain air of uncertainty about them, although there was a fair presumption regarding the character of the disease. To the eye which was at all familiar with the appearance of a tubercular syphilitic, there were certain characteristics by which it could be readily distinguished from lupus. In the first place, there was considerable infiltration of the skin; the lips and chin were very much swollen, and more so than ever found in lupus. Furthermore, it was observed that the border of the eruption was pretty distinctly defined by a series of tubercles, which presented a color quite characteristic of syphilis—namely, a coppery hue. The color was regarded as an important point in diagnosis. Again, they were opaque, and did not have the translucency which was characteristic of lupoid tissue. The extensive infiltration of the skin and subcutaneous tissue, the color and consistency of the tubercles, and the characteristic cicatrices, all pointed to syphilitic lesion, and that character was substantiated by the quite clear history.

CASE II.—A female patient was seen, upon whose face an eruption, for the first time, broke out about a year ago. She was forty-seven years of age; had never borne a living child, but had had one miscarriage at three months. She had had an eruption upon the lips and upon the eyelid for nearly two years, but that of which she especially complained was a group of nodules upon the upper lip, some of which were warty in appearance. There were also a few upon the nose, and with those was associated a hypertrophied condition of the sebaceous glands—many of them being filled with plugs of sebaceous matter. She had had an eruption upon the body, the nature of which had not been determined. No scars had been left, and she had never had pains in the shafts of the bones.

Although there was nothing beyond the fact of having had a miscarriage to point to syphilis, yet it was regarded as quite probable, from the appearance of the tubercles upon the lips, that what we had to deal with was a specific affection. The distinguishing features between such an appearance as this and lupus have already been pointed out; but it was then added that in cases where the evidence of syphilis was incomplete we had a very delicate test in the treatment. For one might be sure, if the lesion was specific in character, that the mixed treatment would produce a marked effect upon it within two weeks. The mixed treatment consists of the administration of mercury, combined with iodide of potassium. Both patients were placed upon the following mixture:

R. Hydrarg. biniodid. . . . . gr. i.  
Potass. iodid. . . . . ʒiv.  
Syr. arrant.,  
Aque . . . . . ʒiij.

M.

S. Teaspoonful three times a day.

It was noted as being a curious fact that intoler-

ance of iodide of potassium was very rare in a syphilitic patient, while in persons in health it was not very uncommon. In health, unpleasant effects were frequently produced by the use of very small quantities of the remedy, but it only occasionally happened that it became necessary to discontinue its use in the treatment of syphilis; for the disease seemed to give the system a tolerance of the drug.

CASE III. was an instance of infantile syphilis, and presented a good illustration of the efficacy of treatment. When about two years old the child exhibited an ulcerating tubercular syphilide upon the body, syphilitic periosteal inflammation of the tibia upon both legs, swelling of the joints, and at the same time cachexia. It began to be ill when about three months old. It was stated to be quite common for children to be born apparently healthy, skin fair, etc., and not present any sign of syphilis until perhaps they were six weeks or three months old. It was common enough, however, for the symptoms of the disease to be present at birth. As a rule, the lesions of infantile syphilis occur from one to three months after birth. The case was interesting in another point of view. There is considerable difference of opinion among syphilographers as to whether inherited syphilis comes from the mother or from the father. Some maintain that the disease always comes from the mother, and in no case directly from the father; in other words, that it is impossible for a child to be born syphilitic without the mother having first had the disease; that, if the husband is responsible for it, he is responsible for first infecting his wife, and that then the wife infects the child. Others maintain that the father may infect the child directly and without infecting the mother. It was believed that those who maintain that the mother must be syphilitic before she can give birth to a child affected by the same disease, certainly have the advantage. For the instances in which the father affected the child without affecting the mother were believed to be exceedingly rare, and it was possible that they were even problematical. Here was a mother who had never presented any evidence of constitutional syphilis, and yet she had given birth to a child that was manifestly syphilitic. It might be explained as an instance of paternal syphilis, but the advocates of the other theory would say that the fact the mother had not presented evidence of syphilis was no argument against the statement that she had syphilis before she gave birth to her child. For many persons were ignorant of the fact that they were syphilitic until some late lesion of the disease appeared. This was said to be true of women much more frequently than of men; for they were frequently syphilitic without ever having had any knowledge of suffering from a primary or even a secondary lesion. The primary lesion had been so trifling that it had passed away without recognition, and the woman remained healthy, comparatively, and for a long time innocent of all knowledge of the fact that she was the subject of syphilitic disease; and she might bear a child which was syphilitic without herself ever presenting special evidence that she was the subject of the same malady. It was believed that the instances, in which it had been said that the children inherited syphilis from the father, were those in which the mother had the disease, but it went unrecognized. The visiting physician was not inclined to believe the theory which claimed that the sperm of the male was capable of extending syphilitic diseases to the children; the mother must first be syphilitic and must communicate the disease to the child if it was the subject of hereditary syphilis. Here the discussion terminated.

#### CATARRHAL LARYNGITIS, OR FALSE CROUP.

To break up the tendency to continuation after the child had had an attack, the following was recommended:

R Calomel . . . . . gr. i.  
 Quinia sulph. . . . . gr. i.  
 M.

To be given three times a day until six grains of calomel had been administered.

#### TREATMENT OF ACNE—FLUSHING OF THE FACE, WITH ENLARGEMENT OF THE SEBACEOUS FOLLICLES—THICKENING OF THE SKIN.

In all cases it was maintained there was a common factor, namely, hyperæmia of the skin. It was important to bear that fact in mind, as it was one of the conditions which should receive special attention in local treatment, and required stimulating applications—something which would produce an active where there existed a passive hyperæmia—something which caused contraction of the blood-vessels. That might be accomplished by bathing the face in water as hot as could be borne. Hot and cold water might be alternated, as in the stimulating plan of treatment for bed sores recommended by Brown-Séquard. The same principle was at the foundation of all the lotions and ointments commonly employed, such as the alkaline lotions and the iodide of sulphur and mercurial ointments.

#### BLOCKLEY ALMS-HOUSE HOSPITAL,

PHILADELPHIA.

#### NOTES IN PRACTICE AND PECULIARITIES OF TREATMENT.

##### EXTENSION IN FRACTURES BELOW THE KNEE.

DR. S. W. GROSS has lately introduced a new method of applying extension in fractures of the tibia and fibula. The foot is well bandaged and covered with turns of a roller. A shingle is then cut to fit the shape of the sole and fastened to the foot by adhesive strips. The weight is attached to a knotted cord passing through the centre of this foot-piece. Pott's fracture is treated in this way, after first bringing the inverted foot into its normal position by a broad adhesive strip running from the inside of and across the middle of the sole, well up on the outside of the leg.

##### GONORRHOEA.

Large doses of cubebs are used in this disease with most wonderful results. So astonishingly rapid and certain are the cures following the prescribed doses of this drug that it has entirely superseded all other modes of treatment. Though of especial value in the acute stage, it has been given with great success in all stages of gonorrhœa. The dose is one tablespoonful four times a day in half a tumblerful of water. It generally cures completely in from three to six days. Chronic cases of course require a longer continuance of the treatment. The above-mentioned doses should be pushed until the bowels are moved, or sickness at the stomach is produced; then the treatment should be stopped, or the dose lessened. Cubebs can be employed without any local treatment, and should be administered only in uncomplicated cases.

##### FRACTURE OF THE CLAVICLE.

The arm is flexed and bound to the body. A silicate of soda dressing is then applied to retain it in position. A pad in the axilla may be necessary in lean subjects. This treatment is much simpler than a

Fox, Velpeau, or Desseau bandage, and is attended with most favorable results.

#### INTRACAPSULAR FRACTURES.

Instead of extension by adhesive strips and the use of sand-bags to keep the fractured limb in position, Dr. Gross has instituted a new treatment. By pillows under the knee the leg is put in the double inclined plane. The adhesive strips are then attached on both sides from the seat of fracture to the knee, and run from there straight out to a pulley and weight at the foot of the bed. This method has been found to act very successfully, and greatly adds to the comfort of the patient.

#### STRICTURES.

Dr. Brinton treats strictures by gradual dilatation—never carrying the dilatation to more than 10; 18 on the scale of Thompson's sound. He uses filiform bougies and Gouley's instrument altogether in small strictures. It is very often found advantageous to retain a soft instrument in the stricture.

Dr. Gross diagnoses position and size of stricture by the bulbous exploring bougie. He does not hesitate to use the urethrotome, provided the man's condition is good and the kidneys normal.

#### TRANSFUSION.

Five of the eight cases of transfusion performed lately at this hospital have succeeded. In one case, a very low stage of puerperal fever, the pulse was reduced from 160 to 120 per minute in a short time. From ten to twelve ounces of defibrinated blood are generally injected.

#### CHRONIC DIARRHŒA AND DYSENTERY.

Dr. William Pepper's use of the Simon gravity injection has been introduced here with very excellent results. The strength of the injection used has been as high as 15 gr. of nitrate of silver to the quart of water.

#### PNEUMONIA.

When the disease is uncomplicated, and the subject plethoric, from eight to twenty ounces of blood are removed by wet cups.

#### ACUTE RHEUMATISM.

Salicylic acid is the victorious cure. Ten grains are given every three hours, and followed in two or three days by the alkalies.

#### LUMBAGO.

The spine is rubbed with ice and atropia, and morphia used hypodermically.

#### PENNSYLVANIA HOSPITAL.

Dr. Hewson treats all fractures of the lower extremities with Smith's anterior splint. Dr. Morton uses Malgaigne's hooks altogether for fractured patella. Dr. Hutchinson uses the following modes of treatment: Acute rheumatism is treated with ten-grain doses of salicylic acid every two hours until six doses have been given; the treatment is then intermitted all the following morning. The urine shows the presence of the acid. In mild cases of typhoid fever, ʒ gr. of quinia and 40 ℥ of muriatic acid are given daily. The body is sponged with cold water. In the second week 10 ℥ of turpentine are given every two or three hours in mucilage, until the tongue grows moist. Chorea is treated in 3 ℥ doses of Fowler's solution, increased 1 ℥ each day, until a point of tolerance is reached. The ophthalmoscope has frequently shown retinal changes in renal diseases. In one case it decisively diagnoses a contracted kidney. Two per cent. injections of carbolic acid are used in paracentesis.

## Progress of Medical Science.

**RUPTURE OF THE VAGINA DURING COITUS.**—A woman of 60, who had been bleeding copiously from the vagina, was recently admitted into the Montreal General Hospital. Her husband, 70 years of age, returning home unexpectedly after an absence of nine years, insisted on having connection with her. She yielded with some reluctance, and the sexual act was attended with great pain, and followed by a severe hemorrhage. Vaginal examination showed that there was a rent about an inch long just behind the cervix in the upper part of the vagina. No further unfavorable symptoms supervened, and the patient left the hospital a few days later.—*Can. Med. and Surg. Jour.*, March, 1877.

**GOUT AND PALMERSTON PILLS.**—Dr. Sorel thus records his own symptoms and the treatment that he has successfully adopted. With a hereditary tendency to gout, he became such a sufferer at forty that six years later he was obliged to give up the practice of his profession. After a series of attacks, in which all his joints in turn were affected, he began the use of the extract of digitalis and the sulphate of quinine. Under these remedies the attacks became less frequent, so that after two years he had but four visitations in the year. Thinking, however, to obviate these entirely, he commenced the use of the pills from two to four weeks before the period at which they were to be expected. At the same time he took active exercise in walking, gardening, hunting, taking daily a little of some diuretic, eating sparingly, taking no spirits, and now his health is excellent, and since 1861 he has had no further illness. As a prophylactic he takes his pills—Palmerston—for ten days every three months.—*Gaz. des Hôpitaux*, 23, 1877.

**THE DIAGNOSIS OF TUMORS OF THE CEREBELLUM.**—Dr. Adolph Ferber deduces the following conclusions from an analysis of thirty-four cases of tumor of the cerebellum, two observed by himself and thirty-two collected from other writers. The characteristic symptoms of tumors of the cerebellum are: 1. Lesions of co-ordination, as expressed by feebleness of movement, unsteady gait, and dizziness. 2. The absence of true motor and sensory paralyses. 3. Occipital pains and vomiting. The diagnosis is supported by the occurrence of difficulty in speaking and swallowing, and by demonstrable ophthalmoscopic lesions. He defines the word co-ordination to be "the harmonious action of several muscles necessary for the execution of a definite purposed movement, concerning alike their number, co-operation, and antagonism, and also the time and the strength of their innervation." He regards the feebleness or slowness of movements mentioned above as an early symptom of disturbance of co-ordination, the nervous impulse not being properly carried to all the participating muscles. He maintains that actual paralyses do not belong to cerebellar tumors. The differential diagnosis is to be made from chronic softening and abscess of the brain.—*Bl. Neulser's Revier in Schmidt's Jahrb.*, 172. iii., 1876.

**DIAPHANOSCOPY IN THE EXAMINATION OF THE PELVIC ORGANS OF THE FEMALE.**—Dr. Justus Schramm has devised an apparatus to be introduced into the vagina so as to facilitate the examination of the pelvic organs from their translucency, as in the familiar case of hydrocele. It consists of a double glass tube, the interior containing strips of platinum, which can

be heated to incandescence by wires, connecting with a battery, which pass through the handle. Water circulates in the space between the two tubes, being brought in by one rubber tube, and carried off by another. When this is introduced into the vagina and the connection made with the battery, the hypogastrum is said to shine like a red paper lantern, the internal sexual organs being outlined like silhouettes upon the uniformly red abdominal wall. Luzarewitsch claims to have made out various pathological conditions by the shading of the colors, but Schramm could not verify these results, though he thinks the plan has some diagnostic value.—*Deutsche Ztschr. f. pr. Med.*, 32, 1876.—*Schmidt's Jahrb.*, 172, iii., 1876.

**CHRONIC INFLAMMATION OF THE KNEE-JOINT CURED BY INJECTION OF IODINE.**—Prof. Weinlechner reports the case of a coachman of thirty-three, suffering from inflammation of three months' standing of the left knee-joint. This knee had been injured by a fall two years before. There was swelling, elevation of the patella, and distinct fluctuation. Treatment by cold and subsequently painting with iodine did not cure it, and on June 23d there was distinct crepitation, and vegetations could be felt on the edge of the capsule of the joint. With a Dieulafoy's syringe two ounces of synovial fluid were first removed, and then a like quantity of equal parts of tinct. iodine and water with some iodide of potassium injected. About an ounce of this fluid was withdrawn after half an hour. The limb was put up in pasteboard splints, and ice compresses applied. There was soon full reaction, the temperature reaching 102° F. After the fourth day the inflammation and fever subsided, and when the dressings were removed on July 31st, the swelling had disappeared. By August 24th there was no more pain, the leg could be fully extended, and bent to a right angle.—*Bericht der k. k. Krankenkunstalt Rudolph Stiftung*, 1875.

**THE SERRATED SCOOP FOR THE DETACHMENT OF SESSILE UTERINE FIBROID.**—Dr. T. Gaillard Thomas has devised a new instrument which he has successfully used to remove a fibroid tumor weighing seven and a half ounces. The patient had been suffering four years from profuse menorrhagia and metrorrhagia, and had been so much reduced in health and strength that she was generally confined to her chamber, and suffered from oedema of the feet, palpitation of the heart, and dyspnea upon the slightest exertion. Examination showed that the growth was not attached along the anterior wall, but along the posterior to within one inch of the os internum. An operation being deemed advisable, the patient was placed in Sims's position, and his speculum was introduced; the lips of the cervix were then severed, and the tumor being exposed, vulsellum forceps were firmly fixed in the growth. The serrated scoop, shaped like the bowl of a spoon, and armed with short teeth along its edges, was then introduced, and with a sawing motion the detachment was readily made in a few minutes. This operation, by the ordinary methods, would have required half an hour at least. The patient since has done well.—*New York Med. Journal*, March, 1877.

**THREE HUNDRED ADDITIONAL CASES OF OVARIO-TOMY.**—Mr. Spencer Wells has furnished a table of the results he has obtained in three hundred cases, from his five hundredth to his eight hundredth. The mortality in the fifth series of one hundred cases was twenty-eight; in the sixth and seventh, twenty-four. He stated that while puncture and drainage, with or

without antiseptic injections, were sometimes called for after operations, it did not follow that preparation should be made for these procedures at the time of the operation. Of these three hundred cases he only made provision for drainage in eight, and in only eleven other cases did fluid afterwards escape by opening of some other portion of the wound, or by puncture of the vagina. In some few of the fatal cases he thought either primary or secondary drainage might have been useful; but it should not be a general practice in ovariectomy, but only be reserved for the exceptional cases where collections of blood or serum might be expected. Of the last twenty-seven cases, in the commencement of his eighth series, none had died. He had thought seriously of trying this hundred cases with every antiseptic precaution, and if he had done so, the conclusions might, from present indications, have been regarded as startling.—*Br. Med. Journal*, March 3, 1877.

**THE LESIONS OF PERTUSSIS.**—At a recent meeting of the *Académie de Médecine*, M. Gueneau de Mussy presented some specimens removed from cases of whooping-cough by M. Parinaud. They consisted of the tracheo-bronchial glands, which were enlarged and compressed, the pneumogastrics and their laryngeal branches. He thought these specimens confirmed his theory that the special form of the cough in pertussis is due to the compression of these nerves by the glands. This theory explains the fact that the spasmodic cough does not occur at the outbreak of the affection, and also the fact that all diseases which are attended by tumefaction of the bronchial glands are characterized by a cough similar to that of pertussis. The reason why this anatomical lesion has not been more frequently discovered is that it has not been looked for. M. de Mussy added that he regards pertussis as a veritable eruptive fever of the variety he has termed enanthematic, and that its contagious power is similar to that of other affections belonging to this class.—*Journal de Méd. et de Chir.*, Feb., 1877.

**PREVENTION OF EPILEPTIC FITS.**—Prof. Nothnagel, of Jena, reports the case of a woman who has suffered from epilepsy gravior for eighteen years, and who is able to ward off the attacks by swallowing a handful of common salt. The attacks are always preceded by an aura which lasts from fifteen to thirty minutes. It consists of a sensation of anxiety and oppression in the epigastrium, which ascends behind the sternum to the neck, causing a sighing and rapid respiration; the sensation then descends, and this may be repeated several times before it finally ascends to the head. When she finds this aura coming on the patient puts a handful of salt in her mouth and washes it down with some water; generally, as the burning sensation in the oesophagus, caused by the salt, descends, the anxiety disappears. Should she be unable, however, to obtain the salt at the moment, the attack is sure to follow. It is well known that, when the aura begins in one extremity, the attack can be occasionally warded off by the application of peripheral irritation, for instance by a ligature to the extremity. In this case it is very probable that the anatomical seat of the abnormal sensations that constitute the aura is in the vagus. Now, the act of swallowing the large quantity of common salt causes an energetic, sensible irritation, which affects the terminal branches of the vagus in the oesophagus and stomach, and hence we have a process which is entirely analogous to the peripheral aura and its cure by the application of a ligature.—*Allg. Med. Central-Zeitung*, Feb. 3, 1877.

# THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

W.M. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, April 21, 1877.

## THE PROSPECTIVE PHARMACOPŒIA.

HAVING in our last stated Dr. Squibb's views, we will to-day consider Dr. H. C. Wood's objections. Dr. W. thinks if Dr. Squibb's plan is carried out that there is great danger of there being two Pharmacopœias, or if not, that the one of the Am. Med. Assoc. will probably fail to command respect, *i.e.*, will not be a good one. It is much better, he thinks, to stick to the old plan, and, in arriving at an opinion concerning the present method, we must judge it in a measure by its fruits. "When we look at American pharmacy, which has grown up under the shadow of this system, we find it peerless among nations;" says Dr. Wood. Upon this point we most humbly beg to differ. On the contrary, we believe it to be the most scandalous pharmacy in the civilized world. Not one druggist in ten has accurate weights or suitable balances; not one in ten is capable of determining the quality or purity of the drugs he dispenses; not three in ten will prepare the same prescription exactly alike, unless its ingredients be chemical salts. Some druggists prepare their tincture by Troy weight, others prepare theirs by Avoirdupois. When we turn to fluid extracts we find it much worse. Very few apothecaries prepare them at all. They buy them from the wholesale manufacturers, whose principal aims appear to be to undersell their rivals. Each one employs a different process, which he advocates as superior to those employed by others. What, then, is the inevitable result? Naturally a very great lack of uniformity in the products of different houses. In fact, we can hardly find two fluid extracts of the same name that are exactly alike in their physical appearances or therapeutical properties. Take the whole line of pills, and the same criticism will apply. These are but a few of the abuses of American pharmacy, and if Dr. Wood points to them with pride as legitimate offsprings of the present

pharmacopœial system—and to a certain extent they are—we can but wonder what the next ten or twenty years will bring forth under a continuance of the same system, and the fostering care of such an advocate. The Pharmacopœia "is certainly very good," says Dr. Wood, and yet there is not a line in it that will aid the druggist in distinguishing rhubarb from squills, either as regards the crude drugs, or their various preparations—not a line that will enable him to judge of the imperfections of an official product, in the preparation of which he may have inadvertently committed an error. These, moreover, are not the only defects of our Pharmacopœia. Others even more glaring might be mentioned, but space will not at present permit. We may be told, however, that these various omissions are fully compensated for in the Dispensatory. This we admit in a measure to be true. For years the Pharmacopœia has been kept a skeleton, in order that the flesh, blood, and brains of pharmacy could alone be found in the Dispensatory, that its owners might reap great profit thereby. We cannot wonder, then, that the heir-apparent to the Dispensatory desires that this state of affairs shall continue. Nor are we surprised by the disingenuous and sophistical arguments that he brings forward in support of his position.

Dr. Wood thinks that Dr. Squibb has maligned the last committee, and has intimated that "they betrayed their trust, and used their position to place the book where they knew it would not do the most good for the cause."\* In this we think that Dr. Squibb is clearly in error, for the committee certainly did place the book where they knew it would "do the most good for the cause" of the Dispensatory.

Dr. Wood's last objection † to the new plan is the fear that Dr. Squibb may be chosen by the American Medical Association as its representative in the proposed Pharmacopœial Council. Upon the propriety or impropriety of such a choice, we do not care to offer any suggestions, believing that the individual members of the profession throughout the whole country are abundantly able to decide the question for themselves.

Dr. Wood concludes with the following quotation from Scripture: "Thou shalt not covet thy neighbor's goods." We fail to see the application of this to the matter in hand, unless it be that the Pharmacopœia as well as the Dispensatory belong to the Drs. Wood, and that vested interests should be left undisturbed, even if the profession and the people of this country are to suffer in consequence.

We trust, therefore, that when the representatives of the profession are in June next called upon to exercise their judgment in deciding this controversy—for such Dr. Wood has made it—that they will carefully consider not only the main question of measures, but

\*Dr. Wood's pamphlet, page 5. † *Op. cit.*, page 11.

the no less important ones of men and motives, and that before deciding they will carefully peruse the pamphlets of which we have given a brief résumé. Dr. Squibb's will be furnished by him upon application, and Dr. Wood's upon the receipt by him of a "three-cent stamp," the postage thereon being one cent.

#### MEDICAL PROVIDENT SYSTEM.

THE recent effort made in this city by the Public Health Association to initiate a provident medical dispensary system will attract a good deal of attention. Considering the great abuses of medical charity, which are so patent to all, it is a subject which must be approached with great caution. So long as it may tend to correct such abuses in our dispensary system the movement will be fraught with great good. To make it successful, however, it is necessary that all the officers of the dispensaries should unite upon some plan which shall enable them to draw the line between those who are real cases for charity and those who are able to pay a small sum.

The appointment of a committee by the Public Health Association looks in that direction; and although it is a matter of some doubt whether the object aimed at can be gained, we still hope that some reasonable plan may be developed. We confess, however, that we are not sanguine upon this point. There are too many selfish interests at stake to render any such arrangement possible. If all the medical men connected with our dispensaries would agree only to treat those patients who are really worthy, the remedy would be within reach; but there is such a desire to increase clinical facilities, to establish large dispensary classes, to minister to the clinical necessities of our colleges, that the fact of the patient being able to pay or not is of the smallest possible consideration. This is a subject which we have often alluded to, and which is one of the disgraceful elements connected with clinical teaching in this city. We repeat, if this medical provident system is calculated to correct these abuses, we shall give it our hearty endorsement. In England, where such provident medical system is said to be carried to more or less perfection, and where the membership amounts to more than one hundred thousand persons, the foundation of such success was laid in the dispensary system itself. In fact, the provident measure was an outgrowth from this. We believe that the limit of membership to these English associations is a family income not exceeding thirty-five shillings a week. We must consider, however, that the social relations of England are different from those which obtain in this country; that the division of classes is more distinct; that there is more chance for a line being drawn between those who are respectably poor and those who are able to pay a physician. Still, we believe the experiment is worthy of consideration, and certainly it will lose nothing by discussion. It may

with truth be said that we have so far done very well with our poor without this provident medical system. We must also conclude that the respectable poor have been treated in a private way by physicians as pure cases of charity. We cannot imagine a physician who, because a patient is really poor, will not give his services. If, however, some society can be made to pay these fees to the physician, or secure to the struggling young practitioner a livelihood, well and good. But from the present stand-point of our knowledge of the abuses of medical charity, it must be regarded as almost Utopian.

We should like to see all the dispensaries made medical provident concerns, and believe that those patients who would be entitled to free services on account of extreme poverty would be a very considerable number. But the question comes up, how can this reform be applied to our college clinics?

#### Reviews and Notices of Books.

AN ATLAS OF TOPOGRAPHICAL ANATOMY AFTER PLANE SECTIONS OF FROZEN BODIES. By WILHELM BRAUNE, Prof. of Anatomy in the University of Leipzig. Forty-six woodcuts in the text. Translated by EDWARD BELLAMY, F.R.C.S., Senior Assistant Surgeon to the Charing Cross Hospital, etc., etc. Philadelphia: Lindsay & Blakiston 1877. Royal octavo, pp. 200.

THIS work contains thirty-one elegant photographic plates, which are reproduced on a smaller scale from the large atlas of the author, together with forty-one woodcuts. All of these represent sections from frozen bodies, and give the exact relation of the different organs to each other. Although the larger atlas supplied a want which had long been felt by both physician and surgeon, its necessarily high price placed it beyond the reach of many. In order to make it more widely available this more compact edition is presented.

The importance of an accurate knowledge of topographical anatomy can hardly be estimated. In general such knowledge is founded more on the ability to imagine the relations which different parts of the body hold to each other, than from any accurate idea which may be fixed in the mind. Our author endeavors by his methods of longitudinal and transverse sections to reduce the difficulties of the study to a minimum; to present, in fact, a complete view of all the parts concerned, nothing more and nothing less. In the words of the translator: "By means of the sections found in this atlas, the exact positions and relations of the structures which must be divided or avoided in the course of an operation are indicated, and the track of a bullet or punctured wound suggested. At the same time they afford an absolutely correct representation of the intimate relations of the viscera, of the thorax, and abdomen."

In order, however, to give an idea of the scope of the work, it is necessary to refer to the number and extent of the views presented. Naming them in their order, we have longitudinal sections of the entire bodies of male and female; three transverse sections through the head at different levels, viz., orbital, aural, and dental supero-maxillary; three transverse sections through the neck at the upper, middle, and lower

portions respectively; eleven similar sections from the root of the neck to the floor of the pelvis; a vertical section of an injected knee-joint; also one of the foot; transverse sections of upper, middle, and lower portions of the thigh; also of the upper, middle, and lower thirds of leg; transverse sections of the thorax, showing normal and pathological conditions; vertical section through elbow-joint; also through hand and fingers; transverse sections of arm, forearm and wrist; sagittal sections through the body of a female advanced in pregnancy; and finally, sagittal section through the lower half of the body of a female at full term. Besides these photographic representations, there are, as before stated, forty-six woodcuts illustrating other sections. On each plate the different parts brought into view are suitably indicated, while a detailed description is given in the text. The plates themselves are beautifully executed, and exhibit all that accuracy of detail which we have a right to expect in first-class photographic representations.

As a whole the work cannot fail to meet with a hearty reception by every progressive student of the human body. To the surgeon it is a contribution to the study of topographical anatomy which needs to be known to be properly appreciated. To such practitioners as reside in large cities, where anatomy can be studied upon the cadaver, it will afford a valuable aid, while to such as are without such means of study it is an almost indispensable addition to a working library. Works on anatomy are usually dry and uninteresting, but the study of these plates forms such an exception to the general rule as to beget a certain enthusiasm for the science. Mr. Bellamy has made an excellent and readable translation, and deserves the thanks of his English reading brethren for placing such a valuable work within their reach.

#### A PRACTICAL TREATISE ON DISEASES OF THE SKIN.

By LOUIS A. DUHRING, M.D. Philadelphia: J. B. Lippincott & Co., 1877.

CERTAINLY no more striking evidence of the progress now being made in the study of skin diseases can be offered, than that we have here a large compendious work on the subject, written by an American. The qualifications of the author for such a task are so well known and so generally conceded, that we take up the work knowing that it is at least all that it claims to be, rather than in a spirit of doubt as to its real value. There has until now, undoubtedly, been a decided want for a book in the style of that of Hebra's, which, in less compass, yet in the main covering the same ground, should give a thorough description of skin diseases and their treatment. There were certain objections of greater or lesser weight against all works previously published, and there was really no work which the teacher could unreservedly recommend to the student. The present work, however, we think, answers all requirements, and will prove in all respects satisfactory. The general division of the work reminds one of the classic treatise of Hebra, as the classification proposed by the latter has been adopted with slight changes by Duhring. The first part is, as usual, devoted to general considerations, and is in all respects admirable. The anatomy of the skin is well described and illustrated by very excellent woodcuts; the chapter being, on the whole, one of the most simple and satisfactory with which we are acquainted. In the section upon symptomatology each primary lesion is first tersely defined, and then carefully described, and besides this the synonyms are given. The question of etiology is perhaps one of the most difficult of handling for any author of any part of a treatise on skin dis-

cases, and to it we naturally turn in a curious spirit. The chapter on this subject by Dr. Duhring is very satisfactory in many respects, chiefly from its simplicity. We find in it no useless theorizing whatever, which is the bane of many books, no verbose descriptions of imaginary diatheses, but only a plain statement of such conditions as are found to predispose to or to excite skin affections. The author briefly speaks of age, sex, seasons, and climate, as external causes; and hereditability, predisposition, certain constitutional diseases, and disorders of digestive organs, and pregnancy as internal causes. He in like manner considers external causes; and in brief, in a few pages tells us tersely and clearly all that he is warranted in telling us of this subject. We are pleased to see an excellent chapter on the pathology of the skin, in which the morbid processes incident to it are well but briefly described. The principles of diagnosis and treatment and the elements of prognosis are treated of in a similarly broad and simple manner, and a perusal of the respective chapters will materially assist the student in his studies. In the same terse way the author's reasons for using Hebra's classification are stated, after which it is given in full. We are glad to see that space is not wasted on this subject, and that we are not inflicted with the divisions proposed since the time of Mercurialis. Space will only permit of a general criticism of the work, and there are many points which we cannot allude to. The descriptions of the various affections are given in a simple and graphic manner, and are certainly all that can be desired. The differential diagnosis is carefully worked out, and the treatment fully and plainly given. Indeed, an important feature of the work is its richness in therapeutical detail, and for this purpose it can always be consulted with benefit and satisfaction. We would particularly insist on this point, so vital to the usefulness of a book, and would repeat that we know of none other to which one can refer with as much benefit in the way of clear practical therapeutic directions and detail as to this one. In the descriptions of the affections there is a wonderful uniformity of excellence, and it seems almost invidious to note any one or more in particular, but we feel that we must call attention particularly to the very thorough chapters on seborrhœa, eczema, new growths, and parasites. Certainly that on eczema is admirable. It is seldom our good fortune to meet with so satisfactory a book as the present one. In its clearness of description, its terseness and comprehensiveness it is certainly exceptional, and it will for years take high rank as a hand-book for diseases of the skin.

DEATH FROM CHLOROFORM.—A death under chloroform has lately occurred in the Derbyshire Infirmary. John Holmes, aged 56, a plater on the Midland Railway, was about to submit to an operation for fistula. About three drachms of chloroform had been administered, when violent muscular spasm supervened, the respiration became embarrassed, and death resulted in spite of every effort at resuscitation. The anæsthetic was properly administered, and no blame seems to attach to any one. This case illustrates what we have very frequently pointed out—viz., the great danger of that period of chloroform narcosis which is characterized by muscular spasm. At this time the respiratory muscles, as well as other muscles of the body, are in a condition of rigid tonic contraction, and the dangers of apnoea are added to those which are inseparable from anæsthetization. At these times the administration of chloroform should be entirely suspended until the spasm ceases.—*Lancet*.

## Reports of Societies.

### NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, April 5, 1877.*

DR. S. S. PURPLE, PRESIDENT, IN THE CHAIR.

#### THE OSTEOCLAST.

The subject presented by Dr. C. Fayette Taylor (see p. 241) being before the Academy for discussion. Dr. GEORGE A. PETERS remarked that he had long recognized the desirability of something by means of which a bone could be fractured at the point of election. As soon as he saw the instrument devised by Dr. Taylor, he was convinced that it would accomplish what had been desired, and that it would prove itself to be of great value to the general surgeon. For it was possible to elect the point at which fracture should be made, and with this osteoclast the bone could be broken at that point with certainty.

He had seen the patient referred to by Dr. Taylor, and could confirm all that had been said concerning him. He had a useful limb.

With reference to the apparatus to be employed after the fracture had been made, Dr. Peters was of the opinion that union would have been facilitated, perhaps have been completed within a shorter period of time, had the plaster-of-Paris dressing been employed from the beginning. As to the difficulty in applying a plaster-splint, so as to secure coaptation of the fractured ends at any angle desired, he was of the opinion that there was no practical difficulty at all. Had the plaster-of-Paris bandage been applied at first the boy would have been able to move about, get exercise and fresh air; whereas he lost six weeks by being confined in bed with the splint employed. Besides the hygienic advantages afforded the patient, who wore a plaster-of-Paris bandage, he was also of the opinion that no apparatus could bear a favorable comparison with it for securing complete immobility of the parts after they had been accurately coaptated. Dr. Peters also remarked that he had thought it impossible to use so much force upon the limb without producing some injury to the soft parts; but in Dr. Taylor's case no damage whatever was done, the skin not even showing where the instrument had been applied.

DR. LEWIS A. SAYRE remarked that although Mr. Adams had very much improved the operation of section of the femur, by making it subcutaneous, yet, with all the advantages of Lister's carbolic spray, he should very much prefer that a compound fracture should not be made. If the apparatus brought forward by Dr. Taylor, which seemed to be capable of accomplishing the purpose for which it was made, could be placed upon the thigh so as to fracture the femur near or through its neck, it would be of the greatest possible value. Whether the instrument was capable of producing fracture when the bone had become eburnated could not be stated, but for all ordinary bones it was probably sufficiently powerful. The great object, if fracture was to be produced, was to produce it at the point selected, and the instrument presented was apparently destined to fulfil such indication. If it could be so constructed as to enable the surgeon to produce fracture within an inch of the trochanter minor or higher, its value would be very much increased, for the reason that motion might then follow as the result of the formation of a new joint.

Dr. Sayre agreed with Dr. Peters in the opinion that for the purpose of securing the limb with the greatest possible precision, nothing could take the place of the plaster-of-Paris dressing. An additional advantage afforded by that dressing was that it placed the patient in a condition in which he could avail himself of the best possible hygienic surroundings. That there was no ecchymosis produced was probably due to the fact that the fracture was made suddenly, and the pressure at once removed.

DR. W. T. WHITE referred to a case of accidental fracture of the femur occurring in the Presbyterian Hospital. The fracture was in the upper third, was produced while manipulating the limb, was dressed with the plaster-of-Paris bandage, and made a perfect recovery.

The Academy then adjourned.

### NEW YORK PATHOLOGICAL SOCIETY.

*Stated Meeting, March 28, 1877.*

DR. E. G. JANEWAY, PRESIDENT, IN THE CHAIR.

#### SYPHILITIC TESTICLES.

DR. J. M. WRIGHT presented two syphilitic testicles, removed at different times by castration from a patient 47 years of age. Ten years ago he had a chancre, and in the course of four months after was seized with secondary symptoms. He came under Dr. Wright's care six years ago, with an extensive pharyngeal ulceration, and soon after the healing of the same by an antisyphilitic course, a gummy tumor made its appearance upon the outer aspect of the right thumb. Six months subsequently the right testicle began to enlarge, and at the end of a year afterwards measured ten inches in circumference and five inches in its vertical diameter. Despite treatment, the disease progressed, sloughing ensued, and numerous openings were formed upon the surface of the organ, communicating with necrotic tissue. On June 25, 1875, this testicle was removed. He made a bad recovery from the operation, an abscess complicated with erysipelatous inflammation forming in the right inguinal region. Six months ago the patient again presented himself with the left testicle as large as the right had been, and with the same gummatous degeneration. This organ was likewise removed, and showed a cavity in its substance filled with the ordinary contents of a gummy tumor. The specimen was interesting on account of its great size.

#### SPONTANEOUS CURE OF HIP DISEASE.

DR. GIBNEY exhibited the head of the left femur, illustrating a spontaneous cure of hip disease. It was removed from a boy eleven years of age, who had died of gastro-intestinal disorder. Previous to the latter illness the patient was apparently perfectly well, in fact, had become robust. The deformity of the hip which resulted presented the usual appearances which are referred to dislocation of the head of the femur on the dorsum ilii. On examining the joint at the autopsy the muscles in its immediate neighborhood were well developed, the sinuses which had existed during the progress of the disease had entirely healed, and the bone itself presented no sign of actual disease. The head of the bone was, however, firmly fastened in the acetabulum, a portion of the caput femoris was entirely gone, the remainder being considerably eroded around its whole extent. The real point of interest was the alteration of the relation of the head of the bone to the shaft, so that it assumed the position of a right angle. There was no disloca-

tion present, but the alteration in the angle of the neck of the bone gave a general direction to the limb resembling that deformity. The disease of the hip dated from 1871, and was traced to a fall.

DR. SAYRE remarked that the case was very interesting as proving that morbus coxarius may go through all its stages, and yet recovery take place without operative interference. He asked if there was any hereditary taint in this instance.

DR. GIBNEY replied that such was the statement on the case-book, but such, in view of the mother's delicate appearance, was not very trustworthy.

DR. SAYRE thought that the case was a very good one to prove the propriety of removing the diseased bone by operation, whereby a more useful limb could be secured. There was no question concerning the probability of recovery without operation, but when such recoveries took place it was at the expense of a useful limb.

#### REPORT FROM MICROSCOPICAL COMMITTEE.

DR. J. A. MCCREERY, on behalf of the Committee on Microscopy, reported the tumor presented by Dr. A. H. Smith at the previous meeting to be one of adenoma.

#### TUBERCULAR MENINGITIS.

DR. JANEWAY presented a specimen of tubercular meningitis.

#### EPITHELIOMA OF THE PENIS.

DR. WEIR presented, on behalf of a candidate, a specimen of epithelioma of the penis, for which amputation had been performed. In the course of the history, the difficulties in the diagnosis of commencing epithelioma from phagedenic chancreoid were mentioned.

DR. JANEWAY, in this connection, referred to the case of a policeman who was threatened with dismissal from the force on account of what was supposed to be chancreoid of the groin, but which really proved to be epithelioma of that part. The diagnosis was made with the greatest difficulty. In the course of his study of the case, he consulted certain works on venereal, but failed to find any particular reference to any distinctive marks which might be present. It seemed to him that syphilographers were inclined to ignore the possibility of any mistake, rather than attempt to explain it. A good excuse for such a course might be found in the fact that these cases of epithelioma, when fully developed as such, passed into the hands of the surgeon, and were entirely lost sight of by the specialist.

DR. E. MASON thought it almost impossible to draw a distinction in some of these cases, and gave an illustration in point.

DR. BRIDDON was of the same opinion, and also referred to a case in which the difficulties were strikingly apparent.

#### FRACTURE OF THE INVOLUCREM.

DR. WEIR presented a fracture of the involucrum which he had removed from the arm of a patient of Roosevelt Hospital during an operation for necrosis. The man was formerly a soldier, was thirty-five years of age, and in good condition. On withdrawing the necrosed portion, during the operation, the involucrum was found to be fractured, and was also removed. The latter condition was supposed to be the result of an injury to the arm received three weeks before.

The Society then went into Executive Session.

## Correspondence.

### ERYTHROXYLON COCA.

[TO THE EDITOR OF THE MEDICAL RECORD.]

SIR:—From time to time spasmodic efforts have been made to introduce into popular use the leaves of the *Erythroxylon coca*, or Peruvian coca plant.

The high value of this plant has never been fully appreciated outside its native lands, owing to the condition in which the same reaches the markets.

The leaves of the *Erythroxylon coca* (coca being the name for the plant in the native language), when fresh, look very much like the leaves of the cherry tree, and are gathered several times a year, and are then quickly dried in the sun. They are, when fresh, of a light green color, having an aromatic odor, similar to the spiraea ulmaria, and possess qualities which the plant, when we receive the same, to a high degree is stripped of. By being carelessly packed, and by being exposed to a high and damp atmosphere in the ship-hulls during transportation, a kind of fermentation takes place in the leaves, and they become of a brownish-green color and lose most of their aroma.

When in this state the medical profession has tried the plant over and over again, and, of course, never received the important results of its use as there is claimed for it in its native countries.

In Bolivia and Peru, and in parts of Brazil, the culture of the *Erythroxylon coca* in the different valleys forms an important item in the agricultural economy of the country; the use of the leaf among the natives being almost universal.

The inhabitants of these countries, and especially the native "Caqueroes," chew the leaves, it being nearly the only luxury of diet they indulge in. It is a well-known fact that this people, who live to an average high age, generally retain their mental and physical faculties to their last days. By chewing the coca leaf it is further known that they are enabled for days to travel over rugged mountains, exposed to a burning sun, or to work deep down in the mines for days without partaking of nourishment or sleep, and without showing any great signs of exhaustion.

Alexander von Humboldt, Bonpland, and other scientists, all speak of the coca plant, agreeing that asthma and tuberculosis are unknown among the Coqueroes, and it is praised by many authorities like Tschudi for its ability to prevent, in some degree, the waste of tissue. Tschudi, in his description of the coca plant, narrates that he, on several occasions, partook of coca, and was by its use stimulated so that he could hunt and travel on mountains 15,000 feet above the level of the sea, feeling no necessity for sleep and nourishment; and that he could run and climb in this height without more inconvenience to his respiratory organs than he would suffer on the plains, and without any extra degree of fatigue.

The coca leaves have been recommended in tuberculosis, asthma, dyspepsia, nervous debility, hysteria, and bilious disorders. Practitioners like von Martius and Demarle in Paris, have tried species of well-preserved leaf, and are high in its praise as a tonic.

Lately a process has been under consideration whereby it is thought to preserve the medical properties of the plant; the fresh leaves are with sugar reduced to a pulp and then dried, afterwards pulverized and packed in hermetically closed tin cans. Last October I received, through the kindness of a friend,

some of this preparation sent from Lima, which I made into a syrup and which has been tried by several practitioners of my acquaintance. Several experiments which were made, and which I, when completed, will take the liberty to record in the MEDICAL RECORD, seem to demonstrate the truth of the high therapeutic value of this drug.

FERDINAND LASCAR.

### MYELITIS OF ANTERIOR HORNS.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—Last evening I was looking over Dr. Seguin's recent and admirable monograph on *Myelitis of the Anterior Horns*, and found that he approves of the term *Poliomyelitis anterior*, suggested by some European observer. The word *poliomyelitis* is to me a new one, and I presume the prefix is from the Greek *πολιός*, meaning gray. Now the word *πολιός* is usually applied in Greek literature to that which is gray and venerable from age, and is used in relation to hair more than any other object. It is, moreover, a poetical word really, although occasionally used in prose. The nearest English equivalent is our word "hoary." To my mind, therefore, the word *πολιός* is used in the above compound with manifest impropriety.

The gray matter of the nervous system is often called the *cineritious* substance, from the Latin word for *ashes* or *ash-colored*, and its color cannot probably be better described than in this way. The first part of a compound word signifying inflammation of the gray substance should be a Greek word for ash-colored.

Such a word is *σπῆδος*, which means this very thing, and its cognate word *σποδοειδής* is used in this sense by Hippocrates. The latter word is too long and clumsy, but the former would be good in form and meaning. Another word, with the same or nearly the same meaning, is *τεφρός*. Either of these is preferable in every way to *πολιός*. The compound, therefore, should be *spoliomyelitis*, or *tephromyelitis*, to be defensible.

To object to the Latin word *anterior* would be hypercritical.

I do not wish to appear pedantic, but it is just as easy to be correct as to be incorrect, and a great deal more satisfactory.

Yours respectfully,

ROGER S. TRACY, M.D.

103 W. TWENTY-NINTH ST., March 28, 1877.

### HYDROBROMIC ACID AND QUININE.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—Dr. Forrest has undoubtedly done a good thing in calling the attention of the profession to Dr. Fothergill's recommendation of hydrobromic acid as a means of preventing the tinnitus aurium of cinchonism. He has, however, entirely misunderstood the sense of my communication published in No. 329 of the RECORD. I did not represent hydrobromic acid as dangerous when properly prescribed, but I did point out to the readers of the RECORD the danger of making use of the following prescription, given, I believe, in Dr. Forrest's first communication, without appending to it a proper formula for the preparation of the acid. The prescription is as follows:

"R. Quinine sulph. . . . . ℥i.  
Ac. hydrobromic,  
Aque. aa. . . . . ℥iiss. M.

"Two teaspoonfuls contain five grains of quinine."

This prescription has been copied by physicians in Brooklyn, and I have no doubt in New York and elsewhere, and very unpleasant results have followed, because Merck's strong acid was used by the druggist in making up the prescription.

Physicians in general practice will not, as a rule, write out directions for the manufacture of any article called for in their prescriptions. The druggists are expected to put up the medicine *secundum artem*. Private formulæ, or formulæ that are not accessible to all druggists through some official channel, are discountenanced both by the American Pharmaceutical Association and by the medical societies. So long as there is no official standard for hydrobromic acid, and as there are preparations of different strength in the market, it will be well for physicians who wish to give this acid, to prescribe the articles which in their combination will form hydrobromic acid.

Thus:

R. Potassæ bromid. . . . . grs. clxij. (162)  
Ac. tartaric. . . . . grs. cxcviiij. (198)  
Quinine sulph. . . . . ℥i.  
Aque. . . . . ℥iij.

Mix and filter.

This prescription will give precisely the same result as the above prescription of Dr. Forrest's, when the acid prepared according to Fothergill's formula is used, and there is no danger in allowing this prescription to be put up by any druggist, as the articles called for are all officinal.

Dr. Forrest suggests that "until we have an official preparation of hydrobromic acid, we cannot do better than to use the preparation made according to Fothergill's formula, a preparation so simple that any druggist can make it."

The only objection I make to this proposition is, that serious mistakes will be likely to occur, inasmuch as druggists are not familiar with Fothergill's formula, and unless physicians give the formula with the prescription, which they usually will not do, other and stronger preparations of this acid already upon their shelves will be used.

How often does it occur that the physician does not obtain a satisfactory result from the use of a new remedy, simply because his prescription is indefinite as to the quality of the article prescribed, and how often, too, the physician accuses the druggist of not properly putting up his prescription, when the prescription has not accurately defined the physician's intention in prescribing.

I wrote before, and I write again now, to suggest the importance of an unmistakable definition of every new remedy which the physician embodies in his prescription, both as to the quality and manufacturer, when there are various kinds in the market. For instance, no medicine is more abused than pepsine. There are a score of different kinds in the market, varying as much in quality as in price. It makes a great difference in the result whether Hawley's or Beale's pepsine is used, and yet the cheaper quality will be used unless another variety is specified.

I raise no question at present as to the therapeutical value of hydrobromic acid, and shall give the medicine a fair trial as opportunity is afforded; but in so doing I shall be careful not so to prescribe it as to incur the danger of cantering my patient's throat, or to put his life in jeopardy.

CHAS. W. VROOMAN, M.D.

11 GREENE AVENUE, BROOKLYN, April 10, 1877.

## New Instruments.

### A NEW PROSTATIC GUIDE.

By F. N. OTIS, M.D.,  
NEW YORK.

THIS simple instrument has been contrived for the purpose of aiding in the introduction of the soft rubber catheter in cases of enlarged prostate gland. Not long since I was called to Brooklyn in consultation to see a case of retention of urine caused by prostatic obstruction. The cause of trouble had been recognized, and readily overcome by the surgeon in charge of the case, who had repeatedly passed a Mercier's gum-elastic catheter. On the day previous, however, some change having evidently taken place in the course of the prostatic urethra, all efforts to enter the bladder were unsuccessful. The united endeavors of two experienced and skilled surgeons had failed to get by the obstruction, and relieve the retention. The prostate was about the size of a small orange, somewhat irregular, and largest on the left side. A catheter of the ordinary curve was abruptly arrested midway of the prostatic urethra. A Mercier's gum-elastic was resisted at the same point. A *Squire's vertebrated catheter* was then introduced, and as it was advanced to the point where previously used instruments were arrested, its extremity was deflected abruptly to the left (as appreciated by a finger in the rectum), and passed from thence into the bladder at almost a right angle. After emptying and washing out the bladder through the *Squire's* catheter, it was deemed wise to leave the instrument *in situ*. On the day following some irritation having resulted, it was determined, if possible, to substitute for the metallic instrument a soft india-rubber catheter. This proved somewhat difficult to accomplish. The suppleness of the soft catheter, which constitutes its chief excellence, proved a bar to its entrance into the bladder, as on being pushed down to the point of obstruction, it doubled, and could not be passed. It was then stiffened with a wire guide, bent at an inch from its extremity to correspond to the deflection of the canal at the prostatic portion. This bend, however, interfered with the withdrawal of the guide after the instrument had been carried into the bladder, and it was only after substituting a smaller wire, and experiencing some embarrassment from its want of stiffness that the object was finally accomplished.

The desirability of having some suitable aid in the introduction of the soft rubber catheter under such and similar circumstances, was very evident, and was a matter of discussion at the time. After considering various expedients during the few days following, I finally contrived what I propose to call the *Prostatic Guide*. This was constructed for me by Messrs. Tiemann & Co., and a cut of the instrument is appended. It consists of a slight steel rod, A, eight inches in length, upon which is screwed a spiral ribband, B, five inches in length. The union is strengthened by the projection of the end of the rod into the spiral, for half an inch beyond the screw, C. This spiral ribband is so flexible that it can easily be made to take the curve of the urethra,

or any irregularity in its course which may present. Its small size makes it capable of being easily introduced into Tiemann's soft rubber catheter, and by means of it the catheter may be carried down and along the urethra to and into the bladder, following any deviation in the course of the canal which may be present from prostatic enlargement or other causes. I have had several opportunities of trying it at my clinique in the presence of the class and on private patients, and have found it thus far to work admirably.

The readiness with which the soft catheter can be introduced into the bladder by the aid of this simple instrument, and its easy withdrawal, leaving the catheter still in the bladder, makes me confident that it will be found a cheap and efficient substitute for Squire's admirable instrument, besides enabling the surgeon to make use of soft-rubber catheters, when otherwise it would be difficult, if not impossible.

108 WEST 34TH ST., March 5, 1877.

### ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from April 8 to April 14, 1877.*

HAYARD, V., Asst. Surgeon. When relieved by Asst. Surgeon Perley to report in person to the Commanding Officer, Fort A. Lincoln, D. T., for field service. S. O. 42, Dept. of Dakota, April 4, 1877.

PERLEY, H. O., Asst. Surgeon. Assigned to duty at Fort Pembina, D. T. S. O. 42, C. S., Dept. of Dakota.

### Medical Items and News.

CONTAGIOUS DISEASES.—Comparative statement of cases of Contagious Disease reported to the Sanitary Bureau, Health Department, for the two weeks ending April 14, 1877.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-Spinal Meningitis.	Measles.	Diphtheria.	Small-pox.
April 7 . . . . .	1	2	93	7	33	38	2
" 14 . . . . .	0	2	101	5	38	40	1

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.—The subject for discussion at the next stated meeting will be "The United States Pharmacopœia."

LOUISVILLE HOSPITAL, KY.—The following gentlemen have been appointed resident graduates in this institution: Dr. Walter Izard, of Virginia, Hospital College of Medicine; Dr. Boyd Cornick, Tennessee, Hospital College of Medicine; A. P. Owens, Louisville Medical College; W. H. Barnard, Mississippi, Hospital College of Medicine.

PRESBYTERIAN HOSPITAL.—The Ninth Anniversary of the Presbyterian Hospital was held April 11th in the chapel of the institution. The annual report read upon that occasion showed the hospital to be full and in a prosperous condition. Addresses were delivered by Rev. Drs. William Taylor and Hitchcock.

PROVIDENT DISPENSARY SYSTEM.—The Public Health Association held a meeting April 12th, to consider the advisability of establishing a provident dispensary

system in this city. Mr. James C. Bayles read a report of the committee upon this subject. Considerable discussion followed, in which remarks were made by Drs. George C. Bayles, S. F. Morris, H. G. Piffard, E. G. Janeway, Warner, and many others. A resolution was adopted appointing a committee composed of Drs. S. F. Morris, J. C. Peters, and O'Sullivan, to confer with the medical officers of the different public charities and report accordingly.

**DR. GURDON BUCK.**—At a stated meeting of the New York Academy of Medicine, held April 5, 1877, a committee consisting of Drs. W. T. White and J. R. Leaming presented the following resolutions, which were unanimously adopted:

*Whereas*, It has pleased an All-wise Providence to remove by death our late associate, Gurdon Buck, M.D., an original Fellow of this Academy, therefore be it,

*Resolved*, That the medical profession of this country, and especially the N. Y. Academy of Medicine, mourn the loss of an eminent member and an upright citizen.

He was singularly devoted to the advancement of his profession. He was assiduous in the performance of self-imposed duties of charity at the hospitals and at the dispensaries of this city.

He was ever ready with counsel and support at the medical societies.

His surgical achievements belong to the history of his native land. They were original, practical, and brilliant.

In the galaxy of talent which shone in the old New York Hospital, he stood among the foremost. His patriotism and high Christian character are our worthy example.

*Resolved*, That we tender the family of Dr. Buck our sincere sympathy.

*Resolved*, That a copy of these resolutions be sent to them, and that they be published in the medical journals of this city.

S. S. PURPLE, *Pres.*

H. T. HANKS, M.D., *Recording Sec'y.*

**SPECIALISM AND GENERAL PRACTICE.**—Dr. Frank H. Hamilton, of this city, in the course of an address recently delivered to the Alumni Association of the Medical Department of the University of Buffalo, made the following remarks:

To understand this matter, let us see what has happened within a few years. When I commenced the practice of my profession, and within your recollection, we, who simply called ourselves physicians and surgeons,—general practitioners,—occupied the entire field. There might have been here and there a strolling specialist, but they failed generally to secure the confidence of the people, or to make any dangerous inroads upon our practice. Our legitimate right to the entire territory was practically undisputed. Since then, however, following upon a few established successes, there has sprung up suddenly a great excitement, such as inevitably follows the rumors of the discovery of a new bonanza; and emigrants, with no other capital than a pick and gun, have crowded into the territory, and never so much as saying "by your leave," they have selected their ground and driven their stakes until little or nothing is left to the original proprietors but the barren title of Doctors, and which title is found to have no weight in law as against the intruders. To-day there is scarcely an organ of the body or an anatomical and classified structure into which these stakes have not been driven, and from which trespassers are not warned.

Let us mention a few of these specialties:—For the head there is the oculist, the aurist; the catarrh doctor for the nose; the throat doctor; the dentist, of whom there are several subordinate and separate departments.

There are heart doctors, and lung doctors; and some who include both of these important organs in their practice, and might properly be called chest doctors. The liver is an old claim, which was worked a good many years and then abandoned as being worked out. There are kidney doctors, also; but no one has ever driven a stake into the spleen, although I do not see any good reason why it might not be worked profitably. There are a great many people who are spleeny, and if any one could summon the courage to put up a sign, I am sure he would be well patronized.

There are doctors for the nerves and for the blood; doctors who can expel by their medicines all the bad humors, and leave their patients in good humor. There are skin doctors and bone doctors, spine doctors and crooked-leg doctors, natural bone-setters, hair doctors, and corn doctors.

I have not, by any means, exhausted the list of specialties, which are to-day recognized in medicine and surgery; but I think you will see that there is a good deal of crowding, packing edgewise, and some overlapping, and that not much chance is left for the old-fashioned physician and surgeon.

**CENTRALIZATION IN JOURNALISM.**—The Medical Society of Virginia has acted wisely in incorporating its Transactions with the January number of the *Virginia Medical Monthly*. The Massachusetts Medical Society has adopted a similar policy for a number of years. This is a step in the right direction, but it would be of little advantage to stop here. The question of centralization in journalism is one which we hope will soon follow this period of literary inflation, which seems to have spread with all the vigor of a virulent epidemic over the Old World as well as the New. In spite of the almost certain failure which may be predicted of any new journalistic enterprise to-day, we constantly see additions to a list which has already outgrown the demand for reading matter. This condition of things is brought about, as we have already shown, by personal and selfish motives which alone stand in the way of an arrangement which would enable all parts of the country to be brought into free communication with each other. We commend this subject to the consideration of the association of editors as a fit subject for discussion at its meeting in Chicago this spring.—*Boston Med. and Surg. Jour.*

**A CASE OF ACUTE AORTITIS.**—M. Dujardin Beau metz recently presented at the *Société Médicale de l'Hôpital* some specimens taken, *post-mortem*, from a man who had been under his observation. The symptoms which he had shown were dyspnoea, and pain over the cardiac region. There were no murmur either in heart or aorta, but the urine was scanty, and there was considerable œdema of the lower extremities. The autopsy revealed hypertrophy and fatty degeneration of the heart, with congestion of liver and kidneys, and acute inflammation of the aorta. The internal surface of this vessel was red, rough, and marked by numerous points of ulceration.—*La France Médicale*, 17, 1877.

THE *Lyon Médicale* speaks of a woman who has given birth to twenty-nine children within nine years. All are girls; were born as triplets, and are perfectly healthy.

## Original Communications.

## UNISON-RESONANCE IN AUSCULTATION.

By EDGAR HOLDEN, M.D.,

NEWARK, N. J.

ANY one who has had occasion to examine critically a very large number of persons supposed to be sound (as for the army or in life insurance) must have noticed that in the lungs of many a condition akin to consolidation existed, unaccompanied by outward evidence of disease; that, in fact, actual stasis of circulation of blood and of air existed at one or both apices, or in some part of the lungs, and that without cough, emaciation, irritation, or history of previous inflammatory trouble, a condition was present usually only found in the incipient stage of pulmonary disease. By a fortunate concurrence of circumstances, I have had occasion to verify a long-standing conviction that this state, albeit a frequent one in persons esteemed healthy, is but the nidus of organic disease—that it is, in fact, the pre-incipient state of such disease.

The disappearance of this stasis or passive local congestion in some cases, and its development into full-fledged disease in others, instead of militating against the theory, really tends to confirm it, since everything great in nature had at some time small beginnings, and in all the progressive changes in the body there must of necessity be a time when a very slight influence will determine the direction of the change.

In this instance, increase of nutritious food or of out-door exercise, of mental quietude or healthful change of climate, may imperceptibly convert the condition favorable to disease into one of absolute and positive health. It would not be difficult to select, off-hand, a score of individuals who to-day carry about in their bodies this condition, which lies like a border-land between life and death, a veritable tinder waiting but the spark of a trifling cold to waken it into life, with all the long, slow train of exudation and impairment of function, of imperfect organization and necrobiotic effort at repair, and finally caseous degeneration or rapid dissolution and decay.

If, as can be incontrovertibly proven, this condition does exist and does disappear without our aid or knowledge, may it not be accepted as a dogmatic truth that in all cases of pulmonary disease, such as we are accustomed to include in the term consumption, there is a preliminary condition between health and disease, varying in duration, but always present, which, like the rivulet, may be turned by the hand, but which, become a river, is resistless in its progress? We may not unfrequently find this form of stasis or engorgement arise from sedentary employment, and from long-continued neglect to fully inflate the lungs, and see it speedily disappear under exercise, or the use of the pneumatometer or other device for bringing the disused tissue up to its proper function.

In these cases I have seen persons actually faint or grow dizzy from the unaccustomed supply of oxygen derived from simple forced expansion of the chest. The inference from all this is probably clear, viz.: Detect this condition in all cases, and this scourge of our humanity and bane of our profession is shorn of its terrors.

Working in this direction with instruments more or less complex and made for the purpose, I have ob-

tained such results as warrant the boldness of the views above advanced, but the chief cause of the present article is, that the recent publication in this journal of an accidental discovery, having reference to the early detection of disease, and termed a resonator, has seemed to demand a more elaborate investigation, because giving rise to the question as to how far the principle involved can be applied to diagnosis. Especially is this the case, since any departure from certain precise and definable acoustic principles in the construction of the instrument must result in disappointment. If the reader will recall the experiments of Savart and Helmholtz on the reinforcement of musical notes by hollow spheres, and opened or closed tubes of resonant quality, and permit the following brief description of one or two of them, the acoustic principles alluded to will be clear.

Helmholtz devised certain hollow metallic globes which, when held to the ear, selected and magnified the particular note out of a composite sound or clang with which their cavities were in unison. These he called resonators. Savart, before him, observed that if a tuning-fork was made to vibrate almost imperceptibly, and held over a tall cylindrical jar, into which water was being poured, the vibration became a clear, loud note, when the column of air in the jar had been so shortened by the water as to bring it into unison with itself. It became, in other words, strongly reinforced.

Prof. Tyndall has moreover shown that "the open tube which gives the maximum resonance is exactly twice the length of the closed one," a point of importance in this connection. All sounds, and particularly those of a musical character, may be reinforced by unison-resonance, consonance, or echo.

It is probable that all of these enter into the production and modification of the sounds heard in the chest, whether of health or disease, although the followers of Skoda would concede but little to any except the second, and those of Laennec adhere to the first alone.

Whatever theory we may adopt, however, the points of interest are: 1st. Can we reinforce and magnify the sounds of respiration? and 2d. Will such reinforcement facilitate diagnosis?

Under ordinary circumstances, if in doubt as to the sounds presented to the ear, the stethoscope is resorted to, and a greater intensity and concentration are obtained, the various modifications of the instrument with pleximetre attachments, or as in the timbrometer of E. Houston Fourjett, with separate vibrating bow, being of use to magnify the sounds *after* they have been transmitted through the thoracic wall. The sounds are then easily magnified, but if they, or any of them, can be magnified *before* transmission—that is, from the inside and not from the outside of the chest—is not a step immediately made in advance? for the character of the conducting medium is at once made more manifest, and the râles of the minuter bronchioles are developed to the ear.

The other advantages of such intensification or amplification will be given below. We have seen by the investigations of Savart and Helmholtz and Tyndall that any note may be reinforced; and practical experience shows that this reinforcement occurs if a column of air vibrates in unison with it, or if another note in harmonious consonance is developed near. Every auscultator is aware of the advantage sometimes derived from having the patient count in different tones or in a whisper, and if an octave or two is run upon a flute or Pan's pipes this principle is strikingly illustrated in the greater intensification of some of

the notes and their harmonies. This intensification varies with the condition of the lungs as regards health, and might be made available if both inspiration and expiration could be thus amplified.

In this, indeed, lies the correct key to a pulmonary resonator; both inspiration and expiration must be intensified, and this must be done without disturbance of their proper relation.

Now if a unison-resonance can be developed in continuity with the inspired and expired air, reinforcement will follow, *provided* the notes developed in the chest by each are the same or in harmony with each other, and this will be the case whether we ascribe the tube or true bronchial sounds to the passage of air through them, or, as I believe Spittal asserted (for his original articles are not at hand), to the glottis.\*

Acting upon this principle, the problem is not a difficult one. A soft rubber tube, when blown into with some force, yields a rushing noise at its free extremity, the contained column of air being thrown into vibration. Constriction of the tube increases this sound, and at certain regular degrees of constriction the noise of exit and ingress of air are clearly in harmony. The following figures illustrate this:

Thus A gives harmony, B discordance, and C again yields notes in harmonious accord.

Applying the constriction at certain points in the tube shows the most favorable point for clearness and intensity to be near the proximal end or mouth-piece, and still further experiment that rigid metallic end-pieces, particularly for the distal end, are advantageous. The length of the tube then becomes a question of interest, and a few trials show that four and a half inches, six and a half, eight and a half, and so on to eighteen and a half inches, yield the best results—a fact which is probably explicable on the principle of semi-ventral segmentation of the contained air, as determined in organ-pipes.

Having thus arrived at certain practical data by experiment, it appears that we have as the most perfect resonator a flexible tube similar in size and point of constriction to the trachea, and bearing a certain relation to it in length; and this, discovered by mere accident, is the resonator presented in THE MEDICAL RECORD, as a discovery in physical diagnosis.

Without assuming more than the current knowledge of acoustic principles, and willing to concede possible error in the above explanations, it is yet a fact easily proven by any one who will take the trouble, that if a tube be made constricted as described, so that the sounds made by the egress and ingress of air give the same note or the harmonics of the same note (a point readily determined by the ear), the ear of an observer applied to the chest receives an intensified expression of the original bronchial murmur, even from the minutest ramifications of the bronchial tree. It may be still further observed, that although a tube more than twice the length of the trachea has been advised, yet upon the principle enunciated by Prof. Tyndall, that "the open tube which gives the maximum resonance is exactly twice the length of the closed one," a different length, equal as near as ascertainable to twice the length of the trachea, might be an improvement.

Inasmuch, however, as the trachea is not absolutely a closed tube, but is continuous with the large bronchi,

and they in turn open into smaller divisions, I have been unable to more nearly approximate correctness in this particular.

It becomes now a pertinent question, what can be expected from amplification of the bronchial or tubular sounds?

Obviously we shall have at least as much as we obtain from the transmission of the voice in counting or speaking, and the value of this, under many circumstances, is unquestionable. Inasmuch, however, as the sound is a uniform one, we shall get more, since now we lose much of the good to be derived from the transmitted voice by the fact that the patient cannot always run the gamut in counting to bring out the most favorable tones, and a continuous sound is by the instrument made to replace a broken one of vowels and consonants. The explanation of the whisper, first noticed by Wright (*Univ. Coll. Hosp.*, vol. xv., p. 14), lies probably in the fact of its greater evenness and uniformity.

Of course no amplification of the vesicular murmur can be expected. The very nature of this as now commonly received precludes such an idea, and indeed this fine rustle of mechanical dilatation is obliterated, if the parts are in health. When plastic deposits exist, the crepitant r le speaks for itself to the unaided ear.

Sonorous and sibilant r les are intensified. Dilated bronchi and tubercular cavities are, as they would naturally be, more clearly defined, especially (and a point of importance) as the air in the lungs, backed up by the effort of forced respiration, brings the pulmonary tissue more closely against the thoracic wall, thus affording a more homogeneous conducting medium. Local deposits, obstructed bronchi, pleuritic effusions, and emphysema, intra-thoracic glandular engorgement, and finally the beginning of fibrinous repair in certain varieties of phthisis may be cited as coming within the scope of the principle involved.

Especially is it hoped that the stasis alluded to at the beginning of this article may be the more readily detected, and the always curable stage of consumption found and attacked.

For life insurance examinations the application of the principle will be apparent.

The following cut represents the resonator made for my own use.

## MESSAGE IN WRITER'S CRAMP AND ALLIED AFFECTIONS.

By DOUGLAS GRAHAM, M.D.,

BOSTON, MASS.

As supplementary to the excellent article on *Writer's Cramp*, by Dr. Beard, in the *Philadelphia Medical Times* of February 3d and 17th, the following cases bearing upon the subject may be of interest. The first I found in "Schmidt's Jahrb cher," Bd. 166, page 166, 1875, and the other two in "Virchow und Hirsch's Jahresbericht" for 1874, 1, page 384. There they have been translated from the Scandinavian into the German, and to my knowledge they have not till now appeared in English.

CASE I.—Rossander's case was that of a secretary *et. 52*, who two years ago had the first symptoms of writer's cramp, which then showed itself by fatigue after an hour's writing. Later there was absolute impossibility for him to write at all; he could only

\* Judging from the correspondence of men of excellence and ability elicited by the original article on the resonator, this view seems a tenable one.

hold the pen and make a few strokes, and on attempting to do more the hand was drawn up, and this movement became more violent and was accompanied with pain. The hand and arm were quite strong and normal in every other respect.

The treatment consisted in the use of *massage* twice daily, energetic kneading of the muscles of the hand—of the thenar and anti-thenar, of the interossei and lumbricales; and with a small wooden cylinder percussion of the muscles of the thumb and little finger, and also of the forearm, especially of the pronators and the flexor and extensor carpi ulnaris. At the beginning of the treatment the thenar muscles on being beaten contracted, but not strongly, but the abductors *minimi digiti* did not contract. Later, by degrees, however, it did. Subcutaneous injections of nitrate of strychnia, ten to twelve drops of a one per cent. solution, were also given daily in the ulnar side of the forearm. After one week there was marked improvement, and after four weeks of this treatment the patient was well."

II. "Drachmann's case occurred in a lady 60 years of age, the Countess D., who for eight years had suffered from writer's cramp, with tonic convulsive spasms of the upper arm as well as of the forearm. She could neither write nor take hold of small objects with the right hand. On the middle of the flexor side of the forearm, in the tract of the median nerve, there was felt deeply situated a small spindle-shaped, smooth tumor, pressure on which gave rise to pain, and on strong pressure there was produced severe pain in the fore and middle fingers and in the thumb. Many different kinds of remedies had been tried in vain, and amongst these electricity, baths and embrocations. After two months' treatment with *massage*, without the use of any other means, the patient could write and do all kinds of fine handiwork without fatigue. The neuroma could scarcely be felt."

III.—"Gottlieb's case was that of a woman *æt.* 52, who had suffered from the malady for nine years. She had been obliged to write nine hours daily for two years, at the end of which time the pen fell suddenly out of her hand. At each attempt afterwards to again hold the pen, the hand trembled strongly. The forefinger of the right hand had become quite incapable of holding the pen, and the middle finger was also similarly affected, but in a smaller degree, on account of which the thumb, supported by the fourth and fifth fingers, was brought into use. There was no pain, but a feeling of formication on the dorsal surface of the two affected fingers. Upon attempting to work with the left hand the same symptoms were brought forth, but in a milder form. There was oedematous swelling of both upper extremities, also in the first and second metacarpal spaces; and extending upwards between the muscular interstices of the whole arm were found here and there spots of infiltrated connective tissue, which were painful on pressure,—these were more marked on the right side. There was considerable anaesthesia of the second and third fingers of the right hand.

After thirty-seven *massages* the patient was discharged. The hand was perfectly normal; only on long-continued and forced writing was there felt the least fatigue."

In the two last cases the reporter does not state in what manner the *massage* was used, but in all probability kneading or *petrissage*, and percussion with passive motion, predominated over simple upward friction. When sufficient time for rest has been allowed, and in the absence of spasm, or spasm of the flexors alone

being present, I should think it might be useful to add resisting motion so as to bring systematically into more powerful action the opposing and less used extensors, which would tend to restore harmony of action by a counterbalancing distribution of will, nerve, and muscular effort.

The indications for the use of *massage* in such or any other cases could not have been better laid down than Althaus\* has done in the following words: "A really effective treatment of scrivener's palsy must be an agent which is at the same time both tonic and sedative in its neuropathical effects, which must have the power of restoring the circulation of the blood in the suffering parts to its proper condition; which is capable of promoting the absorption of serous effusions, and will thus cause the nutrition of the mained ganglia to be raised to a normal standard. Such an agent we possess in the constant current," etc.

In Case No. II, *massage* succeeded after ordinary rubbing with liniments and electricity had failed. When neither the constant current nor *massage* alone did any good it might then be well to try both; on the principle of *shotgun* therapeutics, perhaps, it would be better to combine the two on starting. These cases would also furnish strong evidence why the following remarks of J. Russell Reynolds, in his "Clinical Uses of Electricity," at page 79, should apply equally as well to *massage* as to electricity: "By stirring up the nerves and muscles of a limb you may, to a certain extent, act upon the other ends of these nerves—the ends that are in the spine and head, and so you may improve, by careful usage, the nutrition of the spinal cord, or of the brain. There can, I think, be no doubt of the reality of this secondary result." Further evidence of the influence of *massage* in that and other directions, and appropriate to the cases above related, we have in the last edition of the *Nouveau Dictionnaire de Médecine*, page 693: "Trousseau and Pidoux have signalized the violent stimulation exercised upon the nervous extremities distributed in the regions submitted to *massage*—a stimulation which is communicated to the spinal marrow, which in its turn reacts upon the parts to which it distributes sensibility and motion."

"We know the hypnotic action of the slow and gentle frictions to which certain authors have attributed the tolerance of the manoeuvres of *massage* in the first instants which follow the production of a painful sprain; and on the other hand, we also know that energetic pressures determine a local anaesthesia which we sometimes utilize with great advantage. . . .

"*Massage* augments interstitial absorption † not only by the *sur-actirité* impressed upon the returning circulation, but also by dividing to infinity the pathological and normal products accumulated in the muscular interstices and the meshes of the cellular tissue. The dissemination of these products multiplies their points of contact with the walls of the veins and lymphatic vessels, whence result their imbibition, and finally the diffusion of these substances into the lymphatics and general circulation."

An old gentleman, a lawyer by profession, at times suffered from lumbago brought on by over-work, for which, by the advice of his physician, he sought relief from *massage*. While *massaging* him for that, more than once he called my attention to the thumb, fore and middle finger of the right hand, the fatigue of which from writing he was fond of designating writer's cramp, as it was only after several days' rest

† *Medical Electricity*, page 574.

† And *parenchymatous exudation* also, when it exists.—G.

that he could resume the use of his pen. On two such occasions, immediately after prolonged writing, I manipulated his hand and arm thoroughly, and the following day he could use his pen as freely as usual.

A middle-aged gentleman, of vigorous constitution, a lawyer in extensive practice, was frequently obliged to employ an amanuensis for several weeks in order to recover by rest the ability to use his pen. For the general weariness, at such times, when he could he had recourse to *massage*, and at two different times while treating him thus I gave the fingers, hand, and arm more thorough and special malaxation, with the result each time, after two sittings, of his being able the following day to resume his writing with ordinary ease.

Had these two cases not had the intelligence and the means to rest on the first note of warning, they would doubtless have become confirmed cases of writer's cramp. They are the only two of the kind in which I have had an opportunity to try *massage*. No objective symptoms were present, and as rest was indicated more than anything else, I did not trouble them with resisting or acto-passive motion.

Mr. B. is a gentleman of leisure, in fine health, and of unusual muscular vigor. His favorite pastime is music, and he is a skillful pianist, fond of playing the most difficult pieces; but for years the forefinger of the right hand has been a distressing bane to him, for without warning it will, as it were, *miss fire*, flex toward the palm without striking the key-note, and then he has to desist for the time, sometimes for several days. In one week I gave him three *massages* manipulation, percussion and acto-passive motion, but with no benefit, and I doubt if further treatment of the same kind would have been of any avail, as the finger, hand, and arm were perfect and powerful in every other respect. He had tried electricity, rest, and gymnastics.

Over-use of any group of muscles gives rise to similar disturbances, some of which may be relieved by *massage*, as the following cases will help to show. H. W., *act.* 25, enjoys good health, and has strong muscles; by occupation a pianist and astronomer. For a year past, June 23, 1874, his wrists have been weak and lame, which he attributes in great part to the frequent and forced efforts required in elevating and changing the direction of his large telescope, which strains the extensors of his hands very much. He can play but fifteen or twenty minutes on his piano before his fingers and wrists give out from fatigue and ache. No visible or tangible defect could be found save a somewhat constrained, stiff-bent position of the fingers, making voluntary extension difficult and disagreeable.

The treatment for several months had been rubbing with liniments, and half-a-dozen layers of bandage wound around each wrist, without any improvement resulting. These were left off when *massage* was begun, June 23, 1874. The first four visits were devoted solely to manipulation of the fingers, hands, and arms. I find my notes quote Mr. W. as saying that his hands and arms felt stronger after the first handling. At the fifth and subsequent *massages* I added percussion and resisting motion to all the natural movements of the fingers, hands, and arms, but more particularly to *extension* of the fingers, and of the hands on the forearms, and this was carefully kept within the limits of the patient's strength, so that at no time should he be made painfully conscious of his disability, as this would have frustrated the object of the treatment. In thirteen days from his first visit to me he had eight

massages, at the end of which time I again find my notes quote him as saying that "if any one had told him that his wrists and hands could have been made so much stronger as they now were in so short a time, he would not have believed them." He could then elevate and move his telescope about with ease, and play on his piano for an hour at a time before fatigue came on. *Massage* was continued for a few weeks longer, and the patient got quite well, so that he could use his upper extremities *ad libitum* for any mortal length of time. He has continued well, and for his scientific attainments he has recently been employed by the United States government in a situation requiring a man physically perfect.

Dr. F. E. Corey, of Westboro', Mass., very kindly sent me the following interesting account of a case of over-use of the muscles which move the humerus backward and upward, which he treated successfully with *massage*:

Mr. D. C. B., *act.* 66, by occupation a cutter of leather for boots; has worked at this business a long time, following a pattern with his knife by just the same motion day after day. Previous to my acquaintance he has had attacks of lameness in the right shoulder, which have obliged him to discontinue work for weeks at a time. The lameness for which I treated him commenced last winter by a slight pain on making the cutting motion, and it slowly increased in severity until the movement could no longer be made without a degree of pain which led to the discontinuance of his work.

March 23, 1875, he called at my office, and I found that the posterior fibres of the deltoid and the external head of the triceps were considerably rigid and tender on pressure, and the pain of motion was referred mainly to them, though at times the *teres* muscles seemed to be involved. I began the *massage* that day, working in the direction of the fibres involved. After about an hour's manipulation my patient declared he could move the arm better than before, and expressed the belief that this was the proper treatment for him. For about a week I applied the treatment every day, always with the assurance of progress from the patient. After this the application was made at longer intervals until the 19th of April, when my patient could discover no traces of his lameness, being able to carry the arm in every direction without pain. There has been no return of the trouble up to this date August 11, 1875.

In two weeks from the commencement of treatment he returned to his work, before he was entirely well.

DEATHS FROM CHLOROFORM.—Two deaths from chloroform have been recently reported in the London journals. One occurred during an attempted reduction of an inguinal hernia, at the Peterborough Infirmary—the other at the University College Hospital. The last case was that of a woman for whom ligature of the carotid was to be performed for an aneurism of the aorta. The patient suddenly ceased to breathe when laryngotomy was performed. The left innominate vein, as was afterwards discovered, being occluded, some veins crossing the larynx were much dilated. These were unavoidably wounded in the operation, quantity of blood entered the air-passages, and a though it was promptly sucked out, the delay was fatal. The patient had taken but little chloroform when the obstruction to respiration occurred. In neither case is there any report of a post-mortem examination.

## Progress of Medical Science.

ON THE FILARIA HÆMATICA.—MM. Galeb and Pourquier have recently set on foot a series of investigations in the hope of clearing up the mode of origin of the nematoid worms in the blood of dogs. Among the autopsies performed with this end was that of a bitch with pup, whose heart was found crammed with adult filaria. The examination of the blood of this dog revealed, as is usual, the presence of thousands of the embryos of filaria. To the great astonishment of the investigators, however, the examination of the blood of the fœtus also revealed the presence of many of these embryos. This important observation, in their opinion, demonstrates that the embryos of the filaria, which swim about in the blood of the bitch and are provided with a delicate, pointed extremity, are able to pierce the tissues of the uterus and make their way into the fœtal placenta, whence they are swept away by the sanguineous current of the fœtus. This explanation, founded upon a positive observation, destroys completely the theory of a verminous diathesis and of spontaneous generation, by which it has been hitherto sought to explain the genesis of these hæmatozoa.

C. Davaine, in his *Traité des Entozoaires*, says that the nematoid worms, which circulate in all the vessels of certain dogs, are probably the larvæ of the filaria hæmatica. MM. Galeb and Pourquier say that there can no longer be any question of this. When, after a careful dissection, a microscopical examination of the genital apparatus of the adult female of the filaria hæmatica is made, it is easy to follow the development of the egg and the embryo in the ovary; free embryos, perfectly similar to those which circulate in the blood, are always found in the oviducts. The female of the filaria hæmatica is therefore viviparous. It is the belief of these observers that the embryos are never found in the blood of dogs, unless adult filaria be at the same time present in the right cavities of the heart or in the pulmonary artery. Hence the diagnosis of the latter may be made during life from the examination of a drop of the blood.

The female of the filaria may attain a length of twelve and a half inches. The male is smaller and more delicate; it may be six inches in length. More than a hundred may be present in the same animal. Frequently they cause no symptoms at all; sometimes the symptoms are intermittent, and in other cases they cause dropsies or other affections which prove fatal.—*Gazette Médicale de Paris*, February 24th.

A CASE OF SPINAL PARALYSIS IN AN ADULT.—Dr. Tripier, at a recent meeting of the *Société de Sciences Médicales*, presented a man, aged 48, who had always enjoyed excellent health previous to August, 1875, when he was suddenly and without apparent cause seized with paralysis of both lower limbs, accompanied by severe pains in the buttocks, thighs, calves, and feet, and for two days also in the nape of the neck. The bladder and rectum were not affected. The pains after a time became less severe in the right leg, and at the end of three months disappeared entirely from both legs. At this time the power of movement began to return in the right leg, and progressively improved until the time of his presentation to the Society. The paralysis of the left leg, however, persisted, and the entire limb became flaccid and rapidly atrophied. The patient is now utterly unable to move the thigh upon the pelvis, or the leg upon the thigh, but is able to

move slightly the third and fourth toes. All the passive movements can be made, with the exception of complete flexion of the leg upon the thigh. When the thigh is extended the leg cannot be flexed on it beyond an angle of 90°; when an attempt is made to increase this flexion, a marked resistance is felt, and the patient complains of severe pain in the knee. No contractions are produced in the affected limb by galvanic currents, but the electric sensibility of the skin is perfectly retained. For the rest the sensibility to touch, cold, heat, and pain are intact. Tickling the soles of the foot causes only slight movements of the third and fourth toes. When covered, the two legs are equally warm, but when exposed to the air the paralyzed limb becomes colder than the other. When in the vertical position, the skin of this limb assumes a violet tinge, which disappears as soon as the horizontal position is resumed. Micturition is always easy, and the bowels are regular. There are no eschars nor traces of cutaneous lesions. The other limbs are perfectly normal. The intelligence and the organs of sense are intact, and the thoracic and abdominal organs are sound.

The diagnosis of this case is plain. It is evidently an instance of the affection described first by Duchenne, under the name of acute anterior spinal paralysis of the adult. The identity of the malady with the paralysis of infancy has been positively proved by a case observed by MM. Charcot and Gombault, on which an autopsy was held. Fifteen cases of the affection have already been reported.

An interesting fact in this case is the persistence of the power of movement in two of the toes. A localization of the paralysis in certain groups of muscles is sometimes characteristic of the disease in question, and it is fair to assume that a persistence of the power of movement in a few isolated muscles of a paralyzed limb is not less characteristic. The impossibility of flexing the leg completely is a symptom which has never been noticed in any other case, either in children or in adults. Usually the mobility of the articulations of the affected limb is perfect, and, in fact, the ligaments are supposed to be generally more lax than in the normal state. In this case there is no inflammation or swelling of the knee-joint to account for the impaired mobility. It is probably due to a hyperplasia of the myolemma of the triceps, although the tissue of the muscle has undergone a granulo-fatty degeneration, and has perhaps entirely disappeared. M. Charcot has met with this hyperplasia in cases of long-standing atrophy, and MM. Wolkman and Steudner have found it in all stages of the disease. An autopsy, however, is necessary to settle this point.—*Lyon Medical*, February 25th.

REMEDY FOR ASTHMA.—Dr. George H. Stone, of Savannah, Ga., writes as follows: "The following prescription has proved of great value to me in the treatment of asthma. Given in the paroxysm it invariably shortens and very much modifies the severity of the attack.

℞. Muriatic acid dil . . . . . f. ʒi.  
Syrup. simp. . . . . f. ʒi.  
Aque pure . . . . . f. ʒv.

"M. S. Tablespoonful every fifteen minutes until relief."

CAPT. LAHRBUSI, the veteran opium inebriate, of whose life a short sketch was given in a recent number, died April 3, 1877. In a future issue, we shall give the results of the post-mortem examination.

# THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, April 28, 1877.

## THE PRIZE ESSAY SYSTEM.

It is a noteworthy fact that the prizes offered by the various medical associations throughout the country fail to draw out the best talent of the profession, or at least those well elaborated experiences that are justly held to have the very highest value. We have no lack of excellent papers, but their authors seem to think that they will be better rewarded in reading them before this or that congress or association, subsequently to be published in its annals or transactions, rather than by trusting them to the tender mercies of a prize committee, with the privilege, perhaps, if successful, of paying to have them published. It is certain that our prizes do not attract the attention which they should, for, apart from the monetary consideration, the honor of being a successful contestant should go far towards compensating the author for whatever time, labor, or expense he may have devoted to his subject. As the matter stands now, the arena is mostly abandoned to the younger members of the profession, many of whom are only beginning to make themselves known in the medical world. In Europe, matters are quite different, and we often find in the honor lists names that have long been favorably known in medicine, perhaps those of professors in well-established schools, and, indeed, even some of our own countrymen who have reached eminence among us. It has been said that the honorarium is too small in this country, and that if we should increase the amount, so as to equal the great prizes, of Paris, for example, we should have competitors enough. This may turn out to be true, but the experiences of some of our prize committees would not show it. In some known instances, for example, where a special prize has for certain reasons been increased in amount, the competition has been no more active than before; in fact, it has occurred that the larger prizes have not unfrequently been withheld altogether, when an

award would have been made had the amount been smaller, the quality of the competing essays not reaching the standard required for the special sum offered. We will do well to inquire into these matters and see if there are not other reasons that may hinder some from entering the lists.

Perhaps the following incident will illustrate what may sometimes happen: Some years ago an essay was sent by a medical gentleman to a distant town, to be entered for the annual prize of the association, a sum of moderate value. In due time the article was returned with the remark, in an accompanying note, written to a friend who had sent it, that it would probably have taken the prize, but the committee were not certain of its originality. The essay subsequently took a prize of much greater pecuniary value, was published, and has since been extensively and favorably quoted in various foreign journals, as evidencing a very large amount of original work. But one can well imagine the mortification of the unhappy writer in having the results of his work of months, or perhaps years, returned to him with the statement that the committee were uncertain on the question of originality. Did it occur to the committee that they may have had the same doubt about the merits of any other production that was strictly new and unbackneyed?

The question of originality is one that no committee can determine absolutely, for the work may have been done by another than the apparent author, who may, perhaps, have derived all his "novelties" from some unpublished foreign thesis, or have come into possession of it in any other equally nefarious way. This question, however, the committee have no right to decide, as they have no business to assume it to be other than original, in the absence of facts.

Their duty is to know whether or not it is an original production, judged by the ordinary standards, which are probably correct in ninety-nine cases out of a hundred, and are sufficiently so to enable those *litterateurs* who keep themselves *en rapport* with the progress of the special branches of medicine, to say at once This is or is not new. We venture to say that we have in this country a goodly number of men who would be generally recognized as so thoroughly conversant with the literature of the times, that it could be hardly possible to palm off anything on them that was not original, and were any committee-man to have his doubts on the subject of originality, it is clearly his duty to call in one or more of such experts. The practice of medicine has of late years been so subdivided, and each little corner has been so faithfully tilled, that the ordinary practitioner cannot expect to be versed in the literature of every branch; in fact, it is almost as much as any ordinary man can do to keep himself up with one or two of the minor specialties, and attend to his practice at the same time. Nor is it an act of humiliation on the part of the ordinary prac-

ditioner to make an acknowledgment of his ignorance of certain branches; in fact, his candor should oblige him to do so when he is placed in a judicial capacity, and he should not hesitate for a moment to submit his papers to those whom he knows have the requisite knowledge. Statements of uncertainty as to originality on the part of prize committee-men cannot but have a very harmful influence on the competitor, who sees that his only chance of success lies within the narrow sphere, perchance, of the committee's information. One of the first things to be done in this direction is the appointment of the very best possible committee. The post should be of the highest honor, for they are judges standing in a position to decide all claims of excellence, and they should, therefore, be men of general knowledge, delicate discrimination, and strict conscientiousness. If, however, with the use of all these qualities, an improper person succeed in securing a prize, and it is conceivable that such accidents may occur, he stands a still further chance of conviction in the public prints, in which a production worthy of any such prize should be published by compulsion. There is no safeguard so trustworthy as this, for the committee who now inquire into the merits of his work will be augmented to the extent of the circulation of the article, and there will always be some one to remind the author of the precise claims he has upon others, and the amount of his personal contributions.

He would be an extraordinary man, indeed, who at the present day could succeed in cajoling the public into believing that he was guilty of originality when he was not. Nowadays, the merest item of novelty is paraded in the public prints, and is duly labelled and chronicled as such, as it passes from one country to another, whether it occur in an elaborate "Opening Address," a "Thèse pour le Doctorat," an "Inaugural dissertation," or the "Preliminary Notice" of some half-fledged student who, after a few weeks' of study in a laboratory, fancies he has made a discovery.

As to the question of publishing a prize essay, the expense should surely not be borne by the contestant. As the case now stands, if the article were not of immoderate length, and contained but few illustrations, the medical journals would gladly publish it gratis; but there are instances where an article, however good, would be too long, or would require too many illustrations, and the expense of publishing, as a separate production, would be very great. And yet few committees would think of making restrictions as to length or number of illustrations. In such cases clearly, the association should publish it at their own expense, having it understood in their announcement of the prize, that they will only accept articles of a definite number of pages, and will only be answerable for a moderate and definite outlay in providing for the illustrations, if there should be any. There is no doubt that many compete for prizes simply or chiefly for the monetary

consideration, and to force them to publish at their own expense might, indeed, not only rob the unfortunate of all his hard-earned money, but actually put him to additional expense; under such circumstances, we should hardly wonder if competitors were few.

There is another point upon which a good deal is said. The committee, it is usually understood, should have no clue to the authors; indeed, it is distinctly stated by the medical committee having in charge the Boylston Medical Prize that "any clue by which the authorship of a dissertation is made known to the committee will debar such dissertation from competition." In many of the other prize announcements distinct statements are made on this point. At first sight it would appear that this provisional clause is designed to do away with any chance of favoritism, which, perhaps, exerts more influence than we would be willing to acknowledge; on the other hand, there is little doubt but that it tends to narrow the contesting sphere. Good, original work—and this is usually held by all committees to have the first rank—is most apt to be done by specialists in some department, and the relation of cases, or the method pursued, would often show where the man had obtained his training, where he had been working, and finally, in many cases, one would almost know who he was. In fact, in a very large number of instances, it would almost be impossible to conceal from the knowing ones the identity of the man.

This difficulty would, of course, increase with the completeness of the work. Were, on the other hand, names, places, and incidents suppressed in such a way as to effectually screen the author, there would be no opportunity to verify the facts, and they would, in the committee's eyes, appear less weighty. Practically it ought not to be a matter of prime importance to demand that the author should so screen himself as to entirely conceal his identity. The committee should feel able, and be regarded as able, to decide upon the merits of the production apart from any personal considerations.

Any one who thinks for a moment would soon see that our practising physicians, who have long been known in connection with certain specialties, could not give their experiences without the greatest danger of detection.

It is also a matter of the first importance for an association to define clearly what they regard as the height of excellence in a prize essay. We often hear it stated by persons that they wonder what standard the committee will adopt. There should be no doubt or misapprehension on this point. It is universally conceded that original research ranks highest, though it must be based upon a thorough and critical knowledge of what has been done in the same field by others.

The question of originality with some appears to presuppose that a man is to have a laboratory or some other facilities for the pursuit of his study, as a hos-

pital connection or its advantages, as if he had to be a chemist, experimental physiologist, or pathologist. But this is a mistake. Original researches can be just as well carried out in the parlor, office, or the kitchen, and with every degree of success, provided only that the student, commencing with a full understanding of his subject at the point where he is to take it up, has the facilities in his parlor or kitchen for elaborating new principles, and upsetting or re-establishing old ones. This he may do by the careful and systematic arrangement of any cases which have come under his observation, where by taking account of certain groups of symptoms, perhaps not heretofore recognized in the way that he has studied them, he makes them yield definite results. If such conclusions have a very important bearing on the ordinary practice of medicine, their value will be proportionately enhanced.

The student may turn his attention to chemistry, physiology, or pathology, though in each and every department of medicine he will find room for original research. He does not need always to invent new methods. He may pursue old ones, noting his results, and they will be original so long as he does them himself, and classifies and analyses them himself. Negative results are often as valuable as positive ones, and though it is difficult to go over any question, even the oldest, without developing some new point, failure may even take place in this and yet the sum of his negative results will be of more value than the discovery of a single positive fact of minor importance.

These matters call for the serious consideration of our various medical associations, and if some clearer understanding can be reached upon them it will be better for the associations, committee, and contestants.

#### EDITORIAL PUFFING.

GENERALLY speaking, when medical journals claim to refrain from puffing advertisers, they mean what they say, and try to accord their practice with their precept. Occasionally, however, the voice of the tempter is too strong, and they are bought with the price of a puff. An enterprising firm of pharmacists of Boston has recently been successful in this way with some of the most respectable journals in this and other cities. As a strictly business arrangement on the part of the firm it is good enough; but what can we say for such "independent" journals who are bought with such a price? From personal experience with the repeated overtures from this particular firm, we assert that they never advertise on any other condition, and that consequently the appearance of an editorial notice in every journal in which the advertisement appears is by no means a coincidence.

#### ABUSE OF MEDICAL CHARITY.

Now that the profession is so much exercised in the matter of medical charity, it seems to us a good opportunity for initiating necessary reforms. The coming conference of officers of dispensaries, at the instance

of the Public Health Association, should give this subject a most thorough investigation. There is no doubt that ample opportunity will be given for every one interested to express an opinion. From the present outlook it seems as if there is but one necessity, and that is, the correction of these abuses in some way or another. Whether the provident system will meet the end desired is quite doubtful; but the agitation which the subject may receive in consequence of the efforts to establish this scheme will no doubt be productive of great good. We hope that the representatives of the colleges will not be left out, but that they may be called upon to explain why such gross abuses exist in connection with clinical instruction in this city. We are well aware that medical students must have clinical material, and we are equally impressed with the fact that young practitioners should not be cheated out of their legitimate fees.

#### LENGTHENING THE LECTURE TERM.

THE friends of the University of Michigan, and of medical education generally, will be glad to learn that that institution has decided to lengthen its lecture term to nine months. From what we can understand, there is to be a gradation of studies similar to that now in operation at Harvard. Although the extension of the lecture term will begin with the next session, two years' notice of the permanent change will probably be given, so as not to work any discrimination against students who have already begun study. Any who may begin after next term will possibly be required to adopt the three-year course. The advanced stand taken by this school is of special significance. It proves that, despite its recent troubles with Homeopathy, it is able to rise stronger than ever and lead the van of true progress in the West. The profession will unite with us in giving it its hearty endorsement for the measure adopted.

## Reports of Societies.

### MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Stated Meeting, March 26, 1877.*

DR. JOHN C. PETERS, PRESIDENT, IN THE CHAIR.

#### THE STRUMOUS ELEMENT IN THE ETIOLOGY OF JOINT DISEASES—ANALYSIS OF 860 CASES.

DR. V. P. GIBNEY read a valuable paper upon the above subject. The following is a brief synopsis: It was believed that the synonymous meaning of the terms struma and scrofula was generally conceded. Reference was made to definitions of the peculiar condition by various writers, and that given by Haward, in the fourth volume of St. George's Hospital Reports, was adopted: "Scrofula is a disease of children which manifests itself by a peculiar vulnerability and proneness of the subject to chronic inflammation of mucous membranes and skin, of the lymphatic system and bones, which inflammations are characterized by

great pertinacity, and the products of which have a retrograde tendency." The definition was supplemented by that given by Prince, in his pamphlet entitled, "Considerations in Relation to Diseases of the Joints." (Reprint from the *American Practitioner* for Feb., 1877.) He described a condition which might be "inherited and permanent, acquired and permanent, or acquired and temporary."

Dr. Gibney recognized as a factor in the production of a certain proportion of diseases of the joints, that element which had been described under the name struma or scrofula, and gave an analysis of 860 cases. The analysis was made with special reference to the two prominent theories regarding the etiology of joint diseases, namely, traumatism and non-traumatism. Caries of the vertebræ was included among diseases of the joints. Most of the histories of the cases had been taken by men thoroughly imbued with the doctrine that traumatism was at the foundation of a large percentage of this class of affections.

Of the 860 cases no statement had been recorded with reference to the existing cause in 28.

In 252 cases there was record of a fall or other injury to account for the disease. There were 97 cases in which there was reasonable doubt regarding the relation of cause and effect between the injury and the arthritic disease. Such doubt was based upon the length of time that intervened between the receipt of the injury and the development of the disease. Dr. Gibney, therefore, retained the original number, 252, as cases in which traumatism was recorded as a cause of the joint disease.

Excluding the cases in which no record was made with reference to traumatism, and then deducting from the remaining number the cases which were doubtful, together with those which were retained as due to some injury, namely, 97+252, there remained 483, in which no history of a traumatic cause, such as a blow, or fall, or other injury could be traced.

#### FACTS BEARING ON THE QUESTION OF SEX AS A FACTOR IN THE DEVELOPMENT OF JOINT DISEASES.

Some facts were presented in relation to the above question, inasmuch as many had based arguments on the preponderance of the male or the female sex to sustain one or other of the two theories. The argument had been that females were by nature weaker, lead more of an indoor life, and were less exposed to injuries than males, and that because more boys than girls had joint disease, the cause was traumatic, and not constitutional. It was believed that statistics did not furnish exhaustive testimony upon that point. The following were given: Of 4,871 cases of various joint diseases which had been recorded at the hospital, 2,613 were males and 2,258 females.

#### PARALYSIS.

No class of children sustained more falls than paralytics, and they were generally neglected after receiving such exposure to injuries. Yet, out of 4,140 cases belonging to that class and examined at the hospital, only 4 had been complicated with joint disease.

That fact was offered as a topic for discussion.

#### AGE.

Of the 4,871 cases of joint disease already mentioned, 4,140 were under 14 years of age, 4,111 between 14 and 21, and 320 over 21 years of age.

Of the 860 cases of joint disease embraced in the doctor's own analysis, 3 were developed prior to 6 months of age, 41 before the first year, 99 before 2 years old, 559 before 5 years of age, 719 before 10 years of age, and 97 subsequent to 10 years of age. The youngest was two weeks old, and was a case of

synovitis of the shoulder-joint; the oldest was 58 years of age, and was a case of hip-joint disease.

#### DIATHESIS—HEREDITARY AND ACQUIRED.

Under this head were included in the study such diseases as had been actually existing, and which might account for any morbid condition capable of producing the lesions under consideration.

#### DISEASE OF THE SPINE.

The family history had been traced in 51 cases in which traumatism had been assigned as a cause, and evidence of transmissibility had been found 46 times, or 92 per cent. In 27 cases nothing was found which was regarded as predisposing to strumous diathesis; in 32 none was made. Total, 110. In 78 non-traumatic cases there was evidence of transmissibility in 65, or 87 per cent.; family history not obtained in 68. In 23 cases no hereditary taint was found. Total, 169. With reference to *acquired* diathesis, such as might arise from the various diseases of infancy and childhood, it was found that in 72 traumatic cases 9 had followed some of the diseases indicated, which disease could have been the cause of the joint disease.

Of 123 non-traumatic cases, evidence of an acquired diathesis had been found in 41, or 33 per cent.

Among the traumatic cases, 8 were found with both hereditary and acquired diatheses, and among the non-traumatic, 32 were found with both diatheses.

#### HIP-JOINT DISEASE.

Of 253 cases taken from the 860 analyzed, 183 occurred in females, and 170 occurred in males.

Of the 152 assigned to traumatism, 84 were males, and 68 females.

Of the 195 non-traumatic cases, 81 were males, and 114 females.

#### ANALYSIS WITH REFERENCE TO DIATHESIS.

In 135 traumatic cases, there was evidence of hereditary strumous diathesis in 77. In 20 no note upon that point had been made.

In 139 non-traumatic cases, 72 gave similar evidence, and the condition was not recorded in 59.

In 126 traumatic cases, noted with reference to condition produced by other diseases, 5 were recorded as having both a hereditary predisposition and acquired cachexia.

In 146 non-traumatic cases there were 32 which gave histories of both hereditary and acquired diatheses.

#### SYNOVITIS.

Of the whole number of cases (860) there were 140 of synovitis. Of those, the disease occurred 78 times in males, and 62 in females. There were 60 traumatic cases, 70 non-traumatic, and in 4 it was not ascertained.

In 51 traumatic cases inquiry had been made with reference to family diseases, and in 33 there was found some evidence of hereditary diathesis.

In 54 non-traumatic cases the same inquiry had been made, and in 30 the family history was found to be unfavorable.

#### ANKLE-JOINT DISEASE.

Total number of cases 50. Of those 23 were traumatic. Of that number note had been made with reference to hereditary taint in 13, and evidence had been found in 7.

In 15 non-traumatic cases (total number 25) 9 gave evidence of hereditary taint. Two cases were recorded as neutral.

#### RATE OF MORTALITY.

Of the 288 cases of *hip-joint disease*, in 4½ per cent age death occurred from exhaustion; 4½ per centum

died in consequence of amyloid degeneration;  $1\frac{1}{2}$  per cent. from tubercular meningitis, and  $1\frac{1}{2}$  per cent. from other diseases.

Of the 128 cases of *spinal disease*,  $10\frac{1}{5}$  per cent. died from exhaustion;  $5\frac{1}{2}$  per cent. from amyloid degeneration; and  $2\frac{1}{2}$  per cent. from tubercular meningitis; and  $2\frac{1}{2}$  per cent. from other diseases.

Of the 106 cases of *knee-joint disease*, death from exhaustion occurred in  $7\frac{1}{2}$  percentage of the cases; from amyloid degeneration in 2 per cent.; and in 2 per cent. from tubercular meningitis.

Of the 23 cases of *ankle-joint disease*,  $8\frac{1}{2}$  per cent. died from exhaustion, and 9 per cent. from amyloid degeneration.

The percentage of death in the whole number of cases (545) was  $6\frac{1}{5}$  from exhaustion;  $4\frac{1}{5}$  from amyloid degeneration;  $1\frac{1}{2}$  from tubercular meningitis;  $10\frac{1}{2}$  from the first two combined;  $12\frac{1}{2}$  from the three combined; and  $1\frac{1}{2}$  from other diseases.

#### STRUMOUS DIATHESIS DEVELOPED BY JOINT DISEASE.

It had been maintained by Sayre, Holmes, and others, that strumous diathesis might be developed by joint disease, and for the purpose of obtaining some evidence upon that question, an analysis of 320 cases had been made. Of these cases none had been under observation less than six months, and from that to six years.

In 136 cases the strumous diathesis developed while under treatment for the joint disease.

In 184 strumous manifestations, apart from the joint disease itself, were not developed in any portion of the body.

In conclusion, reference was made to the

#### SCORBUTIC DIATHESIS IN CONTRADISTINCTION TO THE SCROFULOUS.

The paper being open to discussion, DR. FRANK H. HAMILTON remarked that, so far as his opinion went, it was in accord with the inference made by Dr. Gibney with reference to struma being a fruitful source of hip-joint disease. The term struma, however, had always had a wide signification, and, as time had progressed, its meaning had seemed to be expanding. Scrofula and tuberculosis had been regarded as synonyms, but precisely what tuberculosis was had not been determined. Dr. Hamilton described struma by its phenomena; the strumous patient, like a plant growing in a cellar, succulent and prone to early decay, was exceedingly liable to disease. The child was born being the possessor of a peculiar condition, or the early experience in life favored the development of a peculiar condition which rendered him exceedingly fragile; he was liable to maladies of all kinds. In infancy the condition manifested itself by tegumentary eruptions, such as were seen upon the face, head, behind the ears, etc. As the child advanced in life the condition manifested itself in other structures, and more especially the mucous membranes, and he suffered from various catarrhal affections.

Still later in life the condition manifested itself in disturbances of the lymphatic system, and finally, in all probability, as tuberculosis of the lungs and other structures of the body. That was what he supposed was meant by the term "strumous diathesis." It was a peculiar condition, not susceptible of exact definition, but such an one as rendered the system exceedingly fragile. It was the condition which was a prolific source of many diseases, especially chronic maladies. The vast majority of chronic maladies, and many of the acute, in all probability depended upon constitutional fault. Now, what reason was there to

suppose that such condition might not affect the joints of the body, and produce maladies there with as great frequency as elsewhere in the body? There were certain constitutional maladies which had assailed the joints—for example, pyæmia—and had any one given a satisfactory reason why they did? In that instance we had an illustration of a constitutional malady producing a local disease, manifesting a preference for a local habitation, selecting a special part of the body to attack. Syphilitic disease by preference attacked certain parts of the body, and yet no one had given the reason why. Dr. Hamilton wished to be understood as holding to the opinion that chronic local maladies, as a rule, were associated with, and had as a cause which led to a persistence of the malady, some constitutional fault. Why should the affections under consideration, those local maladies, constitute an exception? As an argument upon the opposite side, it had been urged that the joint disease did not occur except after a certain period of life; not until the child began to walk, and when he became exposed to unusual accidents. That was unquestionably true, and the argument had weight. The local disease preferred those periods of life in which traumatism was most active. But, on the other hand, constitutional maladies had always shown preference for certain periods of life for the development of certain difficulties. In infancy the strumous element might manifest itself in phlyctenular affection of the eyes; a little later in nasal catarrh and conjunctivitis; still later in disturbances of the lymphatic glands of the neck, and ultimately the lungs and other parts of the body. The same tendency on the part of constitutional diseases to prefer certain structures of the body at certain periods of life, was so manifest that a great deal of the force of the argument in favor of the proposition that joint diseases were essentially local affections was removed. No good reason could be shown why a constitutional fault might not exhibit a preference for the joints at certain periods of life. That was the line of argument naturally suggested and which left the responsibility upon constitutional conditions, but which did not exclude traumatic influence. The real difference of opinion between Dr. Sayre and himself, relating to the etiology of joint diseases, if any difference existed, was simply a difference with reference to the degree or extent in which the two agents, constitutional condition and traumatic influence, were responsible for those results. Dr. Hamilton inclined to the opinion that joint disease had its origin in traumatism more frequently than the results of the analysis made by Dr. Gibney seemed to show. Dr. Hamilton reached the conclusion that a person receiving an injury about a joint at any period of life would recover much more promptly and certainly if he had a good constitution than if suffering from some dyscrasia. In many cases the injury persisted and the constitutional cause must be considered as dominant. A great majority of cases, in some sense, had a traumatic origin. Nearly all cases of joint disease demanded constitutional treatment, but if the local disease became the preponderating condition, local treatment also would be required.

It had been urged that the local disease itself was capable of developing that very condition which had been called struma. The Doctor believed, however, that the real distinction to be borne in mind was how much weight should be given to constitutional causes and constitutional treatment, and how much to local causes and local treatment.

DR. LEWIS A. SAYRE asked Dr. Hamilton whether he believed it to be possible for a person with a per-

fectly sound constitution to suffer from chronic joint disease.

Dr. HAMILTON answered in the affirmative.

Dr. SAYRE continued by saying that he was glad to know that Dr. Hamilton took that view of the question, for it was a view which he himself had long entertained. He had reached such conclusions from observing the facts relating to cases which had fallen under his observation. There should never have been any dispute regarding the power of constitutional dyscrasia and local injury in the production of joint diseases. The view which he held regarding traumatism in the production of diseases of the joints, was simply that an injury was capable of producing such disease in a perfectly healthy individual, and in such cases was the primary cause; and also that an injury would produce joint disease much more easily in a person suffering from struma, and was the starting-point of the disease in a very great majority of such cases. One reason why struma and joint diseases were seen so frequently in the same person was because a very slight injury—indeed, the slightest the more serious oftentimes, for the reason that it was not properly cared for—might develop the disease in the strumous subject, whereas the same amount of injury to a healthy person would be received without producing any bad effect whatever. The ridiculous statement had been made that he entertained the view that a person who had tuberculosis or struma, or was serofulous, could not have hip disease, white swelling of the knee-joint, or Pott's disease. A great deal of the difference of opinion concerning the relative influence of constitutional and local causes in the production of diseases of the joints had grown out of the fact that some men would persist in misunderstanding him with reference to his real views upon the subject.

It was possible that another misunderstanding had occurred, judging from the doctrine which Dr. Gross, of Philadelphia, advanced before the Centennial Medical Congress, when discussing the plaster-of-Paris treatment for Pott's disease. Dr. Gross had taken the ground that it was absolutely impossible for any person to have genuine hip-joint disease without having inherited serofula; in other words, there was always present a tuberculosis diathesis. It was for that reason that he asked Dr. Hamilton the question, and also believed that when Dr. Gross saw what he had said he would be willing to correct the extreme statement he had made.

Dr. Sayre then presented the following statistics, made from his private case books. They were based upon the fully recorded histories of 562 cases of chronic disease of the joints.

In 378 cases the disease was at the hip-joint; in 85 in the spine (Pott's disease), in 65 at the knee-joint, and in 34 at the ankle-joint.

#### GENERAL CONDITION OF THE PATIENT PREVIOUS TO THE DEVELOPMENT OF THE DISEASE.

*Hip Disease.*—In 242 cases the previous general condition was good, in 50 bad, and in 86 there was no record upon that point.

*Disease of the Spine.*—In 53 cases the previous general condition was good, in 9 bad, and in 23 no note had been made.

*Knee-joint.*—In 38 cases the previous general condition was good, in 17 bad, and in 10 unrecorded.

*Ankle-joint.*—In 17 cases the previous general condition was good, in 1 bad, and in 16 unrecorded.

Of the total number, 562 cases, the previous general condition was perfectly good in 350, was bad in 77, and in 135 was unrecorded.

Under the heading "bad" were included all cases in which the patient had parents who were in any way whatever affected by constitutional taint, although the patients, at the time of the receipt of the injury, were in perfectly good health.

Of the 378 cases of hip disease 265 had been traced distinctly to a traumatic origin. In 113 the joint affection had followed other diseases, such as dysentery, measles, typhoid fever, whooping-cough, scarlatina.

Of the 85 cases of Pott's disease 55 had had traumatic origin, and 30 had followed other diseases.

Of the 65 cases of chronic disease of the knee-joint 46 had originated in traumatism and 19 had followed other diseases.

Of the 34 cases of ankle-joint disease 25 were traumatic and 9 had followed other diseases.

Dr. Sayre believed it was shown by his own cases, and also by those noted by Dr. Gibney, that joint disease could be developed in persons who were in a perfectly healthy condition, and he hoped there was no man who was so silly as to deny that the joint disease could be developed by a much slighter exciting cause in a person having a tainted constitution than in one in perfect health. The previous condition was one of vast importance. A perfectly healthy man could receive an injury, perhaps a very severe injury, and soon get well; but the same injury received by a man debilitated by inheritance, or by certain surroundings, might, and probably would, develop serious disease.

With regard to the age at which joint diseases were most likely to occur, he had stated that it was during that period in life in which there was the greatest amount of exposure to injuries, namely, in childhood and early youth. During those periods in life a slight injury was more likely to develop severe results, because extravasations of blood took place more readily; the ligaments, tendons, and all the structures about the joints yielded to very slight strains and blows. There was difficulty in many cases in tracing out the traumatic cause, because the injury had been so slight as to pass unnoticed, the case was neglected, and not until months had elapsed, perhaps, was the true condition recognized. "The less hurt the worse off."

With regard to rupture of the ligamentum teres in dislocation not being followed by hip disease, it was to be remarked that the anatomical condition of the hip-joint was very different in childhood from that present in adult life. The vascularity of the extremities of the bones in the earlier periods of life was so much different from that found in adult life that the fact that morbus coxarius did not follow dislocation at the hip-joint in the adult could not be used as an argument against the doctrine that hip-joint disease had its origin in disturbances of the vascularity of the parts, perhaps much slighter in character, during childhood and early youth. In addition, a severe injury like the dislocation in the adult would be sufficient to attract attention, and measures would be resorted to for its cure, whereas the slight injury, producing slight extravasation in a highly vascular part, would be passed without attracting attention until inflammatory action had been established. With regard to the case of synovitis at the shoulder-joint in a child two weeks old, reported by Dr. Gibney, he was inclined to accept it with a reservation until the history could be obtained, and the question settled whether injury was not inflicted by the accoucheur at the time of delivery.

Dr. KNIGHT believed that there was a primary pathological condition which was at the foundation

of joint diseases, but some slight accident might excite that condition into action and bring about an active local disease. Such pathological condition was not merely from hereditary predisposition, but might be brought about by any weakening indisposition of the system. In treatment, therefore, something more was required than mere local treatment. The children required proper hygienic management, proper nutrition, all of which he believed could be best directed in properly arranged hospitals.

Dr. JACOBI spoke concerning the definition of struma accepted by Dr. Gibney, namely, a certain vulnerability of the tissues in general, which showed itself in a peculiar disposition to chronic inflammation, occurring in the bones, in the skin, in the mucous membrane, in the lymphatic glands, and exhibited the peculiarity that, as a rule, the physician had to deal with chronic inflammation of several of those organs and tissues at the same time.

We hardly spoke of struma or serofula, whichever term was preferred, when we had to deal simply with a number of glandular indurations. We spoke of serofula only when we had chronic inflammation of the glands, complicated perhaps with bone disease, or chronic inflammation of the mucous membrane; and that chronic inflammation was characterized by the peculiar mode in which it progressed. There was no formation of new cellular tissue, as, for instance, in cirrhosis of the liver or lung, but there was, after a rapid formation of new cells, a rapid transformation of those newly formed cells into pus, and there was a repetition of those processes. That was what was meant by struma. Dr. Jacobi disliked the term serofula, but did not object to it, inasmuch as it was so convenient. When he found chronic disease of the bones he was not prepared to say that it was a case of serofula, unless it was complicated by another chronic inflammation. He believed that a number of those cases could be explained in a somewhat different manner, and also believed that Dr. Sayre in his last remark was in the channel which should be followed. Why was it that children were so much more frequently diseased than adults? Although, while such was the fact, it was known that diseases of children were much less likely to be complicated than diseases of adults. It certainly was true that diagnosis in children's diseases was much more simple than in diseases of adults, because there was no chronic disease of the various tissues and organs to render it complicated. A large number of diseases were what might truly be called developmental diseases. Everything which had a rapid physiological development, an active physiological function, was apt to become pathological. The pathological condition was simply an exaggeration of the physiological function. It was because of that fact that children in the first year of life were specially liable to diseases of the digestive organs. It was for the same reason that children under two years of age were specially liable to suffer from diseases of the respiratory organs; and therefore it was also that at certain times during infancy and child-life this or that organ would probably become affected. Convulsions, meningitis, and disease of the nervous system, as was known, occurred most frequently during that period of life in which there was the most rapid development of the cranium and brain. It was also known that while there was a tendency to skin diseases among children, those parts were particularly affected which were the most vascular, as, for example, the head and face, which were so commonly the seat of eczema. Now the principal diseases of infancy and childhood were diseases of nutrition or circulation, or both. Very

frequently disease of nutrition was dependent only on the circulation, and therefore it was that just at such times as nutrition was most active and circulation was most powerful certain parts of the body were most frequently affected. The same was true regarding the bones as was true regarding the brain and cranium during the period of its most rapid development. It had become an established fact that they would suffer most in those parts in which the circulation was most rapid. Reference was not had to necrosis, where the bone died from sheer want of circulation, but it was a fact, confirmed by surgeons, that those parts of bone which had a rapid circulation of blood were most readily affected by disease. The upper portion of the femur was better supplied with blood-vessels than the lower portion. It was a peculiar fact that when we had to deal with bone disease in little children it was almost always an inflammation of the epiphyses. The younger the individual the softer the ossific tissue. We should not forget that when man was born there was only a single epiphysis in which there was a single point of ossification, and that was the lower epiphysis of the os femoris; all the others were soft tissues. In the same degree that the epiphyses ossified, the tendency to inflammation and suppuration of the bones generally would be diminished. Thus it was, for instance, with the head of the femur. We had seen, after birth, an immense epiphysis in which there was no point of ossification; a few years after, the neck became ossified, and the trochanter and head set each up as an epiphysis, and therefore inflammation and suppuration were of more frequent occurrence in the head and trochanter. Thus it was all through the body. The frequency of bone disease in the young was due to the fact that the bone was not only so much softer, but that it was developed very fast; there was a rapid physiological development, and by an exaggeration of the rapid physiological development it became pathological. That explained the larger majority of cases, even of those which were not complicated with inflammation of the lymphatic glands or mucous membranes.

Dr. HAMILTON remarked that inasmuch as knee-joint disease was much more frequent than disease of the hip-joint, certainly of more frequent occurrence than disease of the elbow-joint, it could hardly be explained upon the ground of greater blood supply, for the blood-vessels diverged from the knee, and converged towards both the hip and elbow-joints. If Dr. Jacobi's argument was sound the elbow-joint should be the seat of disease the most frequently.

Dr. JACOBI remarked that the statistics of Dr. Sayre and also of Dr. Gibney had shown disease of the hip-joint to be much more frequent than disease of the knee-joint; perhaps in the ratio of one to five or six. With reference to the explanation to be given to the fact that disease of the knee-joint was more frequent than disease of the elbow-joint, it was to be remarked that what he had already said had reference to only a single factor. It should not be forgotten that the epiphyses of the elbow-joint were small in proportion to the size of the joint: they contained but a small amount of material; were no more than one-seventh or one-eighth of the weight of the epiphyses of the knee-joint, and the whole weight of the body resting on the knee-joints. Great facility was therefore given for constitutional disease to invade the knee-joint, not to speak of the great facility with which local disease could be developed there by injury from falls and otherwise.

Dr. SAYRE remarked that he did not wish to be understood as claiming that no constitutional treatment should be given in joint disease, but he did re

gard open air and a nutritious diet as the very best that could be employed, and that those could be obtained better outside than inside of a hospital, however good the hospital might be. Local treatment placed the patients in such a condition as enabled them to obtain those essentials to healthy nutrition.

DR. L. D. BULKLEY suggested two questions: First, Did the progress of those cases of joint disease which were claimed to be strictly local differ from those which were acknowledged to be of constitutional origin? Second, Had the influence of the rheumatic or gouty diathesis upon joint diseases been observed?

DR. SAYRE answered the first question by saying that there was a marked difference; for those who were healthy, and descended from healthy parents, recovered rapidly, while those who had a constitutional taint get along very badly.

DR. RIPLEY raised the point with reference to the frequency of hip-joint disease, as shown by the tables presented by Drs. Sayre and Gibney, that Dr. Sayre was a recognized specialist upon hip-joint disease, and therefore a proportionately greater number of cases came to him than to the general practitioner. The same was true with regard to the hospital with which Dr. Gibney was connected. As far as Dr. Ripley's experience went, he had found knee and ankle-joint disease much more frequent than hip-joint disease; perhaps in the ratio of ten to one, and believed that his observations would be corroborated by the general practitioner.

With regard to developmental diseases, such as measles, etc., Dr. Ripley believed they were such to a great extent, because they were contagious, and the children contracted them before they were grown up. In certain places, for example, the Fiji Islands, where the measles had not been known, the entire population was affected when the disease was carried among the people; and it seemed to him that that class of diseases developed because they were developed by contagion. They were contagious diseases, and developed in all who were attacked by them.

DR. JACOBI thought he had made himself clear as to what he meant by developmental diseases. The diseases he included under that head were diseases of the growing body, and he had simply appropriated the term developmental because he supposed that it would be understood.

#### NEW URETHRAL INSTRUMENTS.

DR. H. G. PIFFARD, at the close of the discussion upon Dr. Gibney's paper, exhibited new urethral instruments, as follows: a meatometer; fossal sounds; fossal bougies à boules; ivory meatoscopes; and fossal urethrotome.

All of the instruments were 5 centimetres (2 inches) in length. The sounds were conical through four numbers of the American scale; a set of six running from No. 10 to No. 24. The meatometer was conical through ten numbers—from No. 11 to 20—with a line at each number.

The meatoscopes had been made of ivory, because it was believed that particles of dirt could be much more easily recognized upon them than upon hard rubber.

The instruments had been made short because it was believed that they could be much easier handled, both by surgeon and patient, than those having the ordinary length, and also could be more easily carried. Accompanying the instruments was a tape measure divided into millimetres.

The set seemed complete and well adapted to the treatment of strictures in the anterior portion of the

male urethra. They were thought to have a special value over the instruments in common use in the treatment of affections of the urethra of the female.

The Society then adjourned.

## Correspondence.

### ENDOWMENT OF MEDICAL COLLEGES.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—I received this morning a circular from the Alumni Association of the College of Physicians and Surgeons, asking for contributions to a *fund* which is to be applied to increasing the educational advantages of the College. The paper sets forth the amount desired to be raised (viz., \$250,000), the name and address of the treasurer, the trustees of the Association, but not the important fact who is to have the custody of this fund, and its subsequent application. It does not give the information whether a special professorship is to be endowed, or all the present ones aided. In fact, the composition of the petition and statement is vague, rambling, and without definite point, apparently indicating some concealed purpose. I hope it may be in your power to illuminate that document, and thereby benefit our Alma Mater. No doubt there are many Alumni who would like to give, in some proper way, aid to the institution in its efforts to reach a higher plane, and by this means advance the science and art of medicine and surgery; but they require to know more definitely the plan to be pursued, whether this fund is to be merged into the general fund of the College or kept for special use, also what voice the Association will retain in controlling the use of the fund.

The only concession of authority the College at first allowed the Association was, that the President of the Alumni Association might be an ex-officio member of the Board of Trustees. Has the College authority since been more liberal? This was, we know, thought so inconsiderable by the Alumni, and reasonably too, compared with the liberal proposal, that contributions at once ceased to be sent in, and the life of the enterprise became extinct. Unless the powers that be show more liberality to their generous supporters, newness of life cannot be expected. The case will be even worse than if the matter had never been projected, for support will be refused as well, in all probability. Money certainly will be withheld and the fund remain a mere nucleus. Perhaps, though, some expiring members of the Board of Trustees or Faculty who have attained both riches and honors from the Institution may graciously acknowledge their obligations by commendable checks or bequests to complete the fund, but this can hardly be expected if we are to judge of the future by the past. Have the kindness, in behalf of the Alumni, to answer through your journal promptly.

Yours,  
ALUMNUS.

### THE SMALL-FEE SYSTEM.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—I have read with some interest your recent editorials and the letters that have appeared in the *Record* in regard to the action of the New York Hospital Dispensary. It seems to me that so far the system which this institution has inaugurated has not been fairly considered, and that the attacks begun by

yourself and your correspondents are too much of a personal character, while what is needed is an unprejudiced statement of the possible benefits or evils of such a step. Such a discussion would occupy too much of your valuable space, but I simply wish to call attention to the reforms which such a system of Provident Dispensaries would bring about.

At present the poor and middle classes, which, it is claimed, are those who form the *clientele* of the medical men who are to be injured by the small-fee system, do not always go immediately to the doctor when ill, and this person is not called in until the individual becomes quite ill, or unless the case is one of a surgical nature.

We may take the case of John A., who is a mechanic, has four children and a wife to support, and earns two dollars a day. John A. may catch cold and have rheumatism as a consequence. He at first tries domestic remedies, or goes to the corner druggist for a prescription. These do him no good; so upon recommendation of some friend he buys a bottle of "Liver Invigorator," or "Kidney Persuader," and may next seek the electrician, herb doctor, or some other well-advertised individual. John A. is not the only one of this class; others try clairvoyants, cancer doctors, hydropaths, manipulators, electric bathers, *ad infinitum*, preferring to pay very small fees for proprietary medicines, or to impoverish themselves by going to the quacks.

Then, again, there are a large proportion of the inhabitants of large cities who have only the tin sign of the doctor to judge that person's standing by, and as there are a great many tin signs which adorn the outer walls of both the ignorant and the wise, it is not strange that the poor patient may become, after a discouraging experience, rather "disgusted with doctors."

For these people the Provident Dispensaries and the New York Hospital Dispensary will be a great benefit. A well-established and reputable institution where medical advice may be obtained at a moderate fee, is certainly more acceptable to the patient than the quack medicines, the quack doctors, and the large fees of regular attendants, which during the month may amount to a great deal more than room rent.

REFORM.

### ABUSE OF MEDICAL CHARITY.

MR. EDITOR:—Your editorial of last week on the "Abuse of Medical Charity" has the true ring, and it is devoutly to be hoped that you will continue to "preach" upon this subject until the minds of the profession are thoroughly aroused upon it, and a stop, or at least an abatement, is put upon this widespread and constantly increasing evil. It is a shame that so much medical advice and treatment is given gratuitously to people well able to pay for it, and a still greater shame that a considerable proportion of the profession itself fosters and encourages it. There is neither justice nor reason in it, and the half thousand physicians in this city, who are hardly able to earn a respectable living, despite their best efforts, will hail with delight the day when the medical profession ceases to cheapen and belittle itself by encouraging the multiplication of charitable institutions, and offering inducements for increasing the already too numerous army of medical paupers. The abuses of the organized charities of New York are too numerous and glaring to be denied, and the remedy is sufficiently obvious. The harvest is ripe for reform. Will you not, Mr. Editor, thrust in the sickle, and swing it with an unsparing hand, until some means are devised by

which all except those who are absolutely unable to pay *anything* for the services of a physician, or for the medicine which is prescribed for them, shall be debarred from obtaining such services without remuneration?

PHYSICIAN.

NEW YORK, April 12, 1877.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—Allow me to express my thanks for your outspoken opinion of the new departure of the New York Hospital. Indiscriminate charity is making fully one-third of the city's population beggars, and large numbers of persons, well able to pay reasonable fees for medical advice, are availing themselves of the dispensaries, because there they get good treatment for nothing. To my certain knowledge there are persons going there whose bank accounts show thousands of dollars to their credit. This statement I can substantiate by proof that cannot be controverted.

When will these abuses be abolished? When will the so-called philanthropists stop trying to degrade medicine to the level of the trades of bootblacks and tinkers, and ask medical men to live on the same pay? Let the profession stand against it. If *we* do not cure for our interests, who under heaven will?

Very respectfully,  
MEDIC.

### MEDICAL DIARY.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—In the *London Lancet*, *Gazette*, and *British Medical Journal* there is published under the head of "Medical Diary for the Ensuing Week," the day and hour of the clinics to be held and operations performed at the several hospitals of London, together with a notice of meetings of societies, the subjects to be considered, etc. If the RECORD, which is now also a weekly, would publish a similar programme, I feel assured it would receive the hearty co-operation of the visiting physicians and surgeons of our hospitals in giving the necessary information. The invaluable experience afforded by our hospitals only exceptionally extends beyond the favored "visiting and interne," while the "outsider" remains ignorant of what goes on in his midst. Let our hospitals be "free and welcome" to every practitioner, and you will also receive the thanks of the profession at large for your trouble.

Yours truly,

HOSPITAL SURGEON.

[We should be very happy to follow out the suggestion of our correspondent, but the difficulties in the way are very numerous. We have already made an effort in that direction, but have found it impracticable, because of lack of promptness on the part of the proper authorities to furnish the desired information. We hope, however, to be able to perfect some plan which shall go into operation at no distant date, and which shall prove satisfactory to all. To be available, the information must be sent to this office on or before Tuesday of the week of publication.—ED.]

### SULPHIO-CARBOLATE OF SODA IN SCARLATINA.

TO THE EDITOR OF THE MEDICAL RECORD.

EVANSVILLE, April 10, 1877.

In September the 2d, 1876, my article appeared on the above remedy in the *Philadelphia M. & S. Reporter*, vol. xxxv., No. 10. I have since treated six

cases, which confirm my former experience that it acts almost as a specific in this disease, as quinine does in intermittents. All my cases yielded promptly to the following prescription:

- R Sulpho-carbolate of soda..... ʒ iss.
- Aq. flores aurantii..... i.
- Syr. pruni virgin..... ʒ iss.
- tolu..... ʒ ss.

M. et S. Teaspoonful every two hours for children two to twelve years old. I also used the same prescription, a teaspoonful four times a day, as a prophylactic with same good results. All the twelve children who took the medicine escaped the disease, although they lived in the same room with the sick ones.

Respectfully,  
J. PIRNAT, M.D.

713 UPPER SIXTH STREET.

**PUERPERAL FEVER AND POST-MORTEM EXAMINATIONS.**

MR. EDITOR:—Under the above caption, in your March 31st number, it is stated that, at a recent meeting of the N. Y. Pathological Society, the question was asked, "whether it was safe to attend a parturient woman immediately after performing an autopsy?" As the question is a very important one, it may be well to state that, in 1860, I had a case very similar to that related by Dr. Janeway in answering Dr. White's question. I had just finished making an autopsy of a case of peritonitis, in which my hands, and those of my then assistant, Dr. Richardson, of Virginia, had been bathed in the abundant serum for an hour or more, when I was summoned to go four or five miles to attend a case of confinement, where instruments would probably be necessary. There was no physician available but ourselves. Assistance had already been delayed too long, and after several ineffectual attempts to perform version (it was a transverse presentation), I was compelled to resort to evisceration and the use of the crotchet. The operation was a protracted one; but the mother had not an untoward symptom. I thought, at the time, that she had a providential escape; but I am since inclined to Dr. Janeway's opinion, both as regards the *innocuousness* of the post-mortem contamination, and the *danger of the erysipelatos*.

F. D. LENTE, M.D.

PALATKA, FLORIDA, April 3, 1877.

**ARMY NEWS.**

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from April 15 to 21, 1877.*

MAGRUDER, D. L., Surgeon. Assigned to duty as Attending Surgeon and Examiner of recruits at St. Louis, Mo. S. O. 82, A. G. O., April 18, 1877.

ALEXANDER, C. T., Surgeon. When relieved by Surgeon Magruder to report to the Com'd'g General, Dept. of the Columbia, for assignment to duty. S. O. 82, c. s., A. G. O.

WOODHULL, A. A., Surgeon. To report to the Com'd'g General, Mil. Div. of the Pacific and Dept. of California, for duty in Dept. of California. S. O. 83, A. G. O., April 19, 1877.

DE GRAW, C. S., Asst. Surgeon. Assigned to duty at Oglethorpe Barracks, Savannah, Ga. S. O. 76, Dept. of the South, April 19, 1877.

JESSOP, S. S., Asst. Surgeon. Assigned to duty at Charleston, S. C. S. O. 75, Dept. of the South, April 18, 1877.

DE HANNE, J. V., Asst. Surgeon. To report to the

**Medical Items and News.**

THE COLLEGE OF PHYSICIANS AND SURGEONS AND GRADUATION QUALIFICATIONS.—In a recent number of the *MEDICAL RECORD* we referred to certain charges made against the College of Physicians and Surgeons by the *University Herald*, Syracuse, N. Y., regarding the improper graduation of a student at the last commencement. These charges were, that the said student was not twenty-one years of age, had studied medicine but two years, had affixed A.B. to his name without receiving a diploma therefor, and had not attended two full courses of lectures. Immediately after this item was published the college commenced an investigation of the case, sifting the evidence on both sides. The results of this investigation are given in detail in an elaborate document by Prof. John G. Curtis, M.D., Dean of the Faculty. We very much regret that the extreme length of Prof. Curtis's letter forbids its publication entire. A summary of its contents is, however, the best we can do for it under the circumstances of a promise to publish all the facts in the case at the earliest possible moment. Prof. Curtis denies in toto the charges, and proves quite satisfactorily by certificates, affidavits, lecture tickets, etc., that the gentleman in question took two full courses of lectures, studied medicine for the full term of three years, and was past twenty-one years of age at the time he graduated from the College of Physicians and Surgeons. In regard to the title of A.B., its use by the graduate in question (on any occasion while connected with the college) is flatly denied by the Professor. It would appear, then, that the charges of the *University Herald* are without any foundation in fact.

CONTAGIOUS DISEASES.—Comparative statement of cases of Contagious Disease reported to the Sanitary Bureau, Health Department, for the two weeks ending April 21, 1877.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-Spinal Meningitis.	Measles.	Diphtheria.	Small-pox.
April 14.....	0	2	101	5	38	40	1
" 21.....	1	4	102	1	14	56	1

DR. GURDON BUCK.—At the recent meeting of the Medical Board of the Presbyterian Hospital, the following were presented by Dr. A. C. Post and unanimously adopted:

*Whereas*, It has pleased Almighty God to remove from earth the soul of our late associate, Gurdon Buck, M.D.:

*Resolved*, That we highly appreciate the untiring industry, the unflagging zeal, the patient study, the careful observation and accurate record of cases, the sound judgment, the fertility of resources, and the skillful application of the means of relief which raised him to a very distinguished position as a surgeon, and gave him a world-wide reputation in the profession.

*Resolved*, That we entertain a high sense of his executive ability displayed in the organization of the Surgical Department of this Hospital, and of other institutions with which he has been connected.

*Resolved*, That we cherish his memory as that of an upright and honorable man, a good citizen, a faithful friend, and a consistent Christian.

*Resolved*, That we sympathize with the members of his family in the bereavement which they have sustained.

*Resolved*, That copies of these resolutions be sent to the family of the deceased, and to the medical journals of the city.

THE PROGRESS OF HIPPOPHAGY.—Since the siege of Paris the quantity of horse meat consumed in that city has increased yearly. In 1875, 6,865 horses, asses, and mules were slaughtered for public consumption at the horse-shambles, while in 1876 the number had increased to 9,271, weighing 1,685,470 kilogrammes of meat, net. On the 1st of last January there were 58 special slaughter-houses in Paris; of these nine belong to M. Tétard, who has received a gold medal as a recompense for his zeal. The population of Lyons is not as much given to hippophagy. In 1872, 1,262 horses, asses, and mules were slaughtered in the seven special slaughter-houses, but in 1876 the number had fallen to 1,088. In Paris, there are more unfortunate people who are unable to pay the enormous prices demanded for butcher's meat, and are forced to content themselves with horse meat. From a hygienic point of view, it is a great advantage that they are able to obtain this meat; for healthy meat taken from animals that are slaughtered on account of lameness is much more nutritious than a diet composed solely of vegetables, with the addition perhaps of inferior or bad meat.

TREATMENT OF HEMORRHAGIC FEVER.—Dr. W. H. Johnston, of Selma, Ala., writes as follows:

"I have found nothing comparable to diaphoresis in the treatment of this disease, and I carry it out in the following manner, viz.: If my patient is not too weak, I have him placed in a large tub of hot water, and throw a blanket around him, and let him remain for fifteen minutes. Then remove him and wrap him in a blanket, and cover him with blankets, and let him perspire for nearly or quite an hour, giving him bits of ice during the time. The nausea and vomiting will be greatly, if not entirely relieved by this bath, and the yellowness of the skin will also disappear. In the course of two or three hours the urine will begin to grow lighter in color and have a urinous odor, and in ten or twelve hours will be normal. The pulse falls steadily after the bath. A few hours after the bath, I give fifteen or twenty grains of quinine by the mouth, or thirty grains by enema.

"If the nausea returns I repeat the bath. If my patient is too weak to be removed from the bed, I have

a blanket wrung out after having been soaked in hot water, and wrap him in it after removing his clothes.

"I generally give teaspoonful doses of Squibb's fluid extract of ergot every two hours till the blood disappears from the urine.

"Though I believe the diaphoresis is sufficient without this to relieve the whole trouble, my subsequent treatment is quinine daily for a week or more.

ELECTROLYSIS IN OVARIAN TUMORS.—Dr. Paul F. Mundé, 20 West Forty-fifth St., New York, requests any gentleman, who has either met with a case of this treatment himself or knows of one in the practice of a friend, to send him *at once* by mail a short history embracing such points as: age, general health of patient, duration of disease, dimensions of abdomen; number and length of sittings, strength of current used, name or character of battery; needles, where inserted, how many, negative or positive; results, good, bad, and negative; length of time patient remained under observation. Dr. Mundé is preparing a paper on this subject, and is anxious to collect the material "*as soon as possible*" prior to the 10th of May.

MEDICAL WOMAN.—*Nature* announces that the Royal Free Hospital, London, has at length granted woman the privilege of entering the hospital for clinical instruction. It is said that the trustees of the London School of Medicine for Women had resolved to close it, and to recommend their pupils to seek instruction elsewhere than in England, but that this concession of the Free Hospital will prevent the breaking up of the school.

DR. GEORGE H. LAMSON, son of a distinguished clergyman of that name, and who was the only American surgeon in the Servian army, in which he held a responsible position during the late war against Turkey, has had the Gold Cross of the Order of the Tahoo conferred on him by Prince Milan. Dr. Lamson gained valuable experience during the siege of Paris in the American ambulance, under Dr. John Swinburne, late health officer of this city, and where he was also decorated with the Bronze Cross of Geneva.

LARGE HEART.—Dr. W. L. Kelsey, of Willington, Ct., states that the heart of Tully Harbison, æt. twenty-one years, who died suddenly, weighed two pounds and twelve ounces. This is certainly a large heart, but cases are on record in which this organ had reached a much larger size. For instance, Prof. A. Clark, of the College of Physicians and Surgeons, has presented one which weighs fifty-seven ounces. This, we believe, is the largest on record.

AMERICAN GYNCOLOGICAL SOCIETY.—The second annual meeting of this Society will be held in Boston, on May 30, 31, and June 1, 1877. Papers are expected from the following gentlemen: Dr. For-dyce Barker, President; Drs. Robert Battey, Van de Warker, W. T. Lusk, G. H. Lyman, J. C. Dalton, W. L. Richardson, W. Goodell, R. A. F. Penrose, J. R. Chadwick, and many others.

DISPENSARY AND INFIRMARY OF THE CHURCH OF THE HOLY TRINITY.—We learn from the Annual Report of the Trustees of the Dispensary and Infirmary, for 1876, that there were treated at the dispensary, 1,285; at their homes, 291; number of visits made to patients at their homes, 838; number of prescriptions given, 6,349; the cost, \$1,146.28. The medical staff consists of the following gentlemen: Howard Pinkney, Physician in Charge, assisted by Drs. W. W. Strew, Mercy Baker, Howard Pinkney, Charles Milne, S. Hutchings Hurd, I. V. Mott, Robt. Campbell.

## Original Lectures.

## ON CONSTIPATION.

CLINICAL LECTURE DELIVERED IN BELLEVUE HOSPITAL,

By WM. H. THOMSON, M.D.,

PROFESSOR OF THERAPEUTICS IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.

(Phonographically reported for THE MEDICAL RECORD.)

GENTLEMEN:—I will direct your attention to-day to the treatment of constipation as found among males as commonly, perhaps, as among females. The constipation generally complained of in the male sex I divide into that due to deficient action of the small intestine, and into that due to deficient action on the part of some portion of the large intestine.

Deficient action on the part of the small intestine is due to two causes:

1. Deficient secretion;

2. Want of innervation, or want of muscular action.

Constipation dependent upon deficient secretion is quite distinct from that caused by want of muscular action, and yet you will have many cases in which both causes are operating.

Deficient secretion in the small intestine may be caused by some disturbance of the liver. Constipation, therefore, may date from the time when the patient suffered from some severe form of fever in which the liver was prominently involved, such as the bilious remittent; or, it may follow an attack of tropical diarrhoea, which is almost invariably accompanied by marked hepatic disturbance.

In such cases the patient does not have an extraordinary fecal accumulation and impaction, but there is, instead, a sluggish action of the bowels, and they are usually obliged to take medicine to bring about a movement once in four or five days; and when it does occur, the evacuation is moderate in amount, and quite dry.

This kind of constipation is quite common in the Southern States, as a sequence of the diarrhoea which prevails in that latitude; and it is also frequently seen in the Northern States as the result of malarial poisoning.

The symptoms are extremely negative, except the constipation. The one which, perhaps, gives the patient most discomfort, is a tendency to a dull, indefinite headache. In a majority of cases this is located in the posterior part of the head, is rather an uncomfortable sensation than a real pain, and is best relieved by something which promotes a free discharge of bile. The tongue usually is small, not large and flabby, generally a little reddened along the edges and tip, and the secretions of the mouth are commonly viscid. The condition of the mouth is an indication of the condition present along the entire alimentary canal. We have, therefore, evidence of the presence of only a moderate amount of secretion in the intestinal tube, and our treatment should be regulated accordingly.

If, for the relief of this condition, you administer mild cathartics, the condition of the case will be aggravated, because the temporary stimulus afforded by them, however mild, is immediately overcome by the tendency to deficient secretion. Active purgation produces a much more injurious effect than mild laxatives. If you resort to the use of medicines which have been recommended to stimulate nerve action, you will not obtain much benefit. What you wish to have present in the intestine, is a small increase

of lubricating substance, as it were, and, to that end, I have found altogether the best results have been obtained by causing the patient to take a great deal more water than is his usual custom. Let him take, on rising in the morning, two tumblerfuls of Croton or other drinking-water. As a rule, those who drink considerable water are not troubled with constipation. You can insure the laxative action of the water by the addition of some mild saline, like the carbonate of soda, or even common salt, and the reason why such an effect is produced is this: the mixture formed by the union of some saline with water, does not readily pass through the mucous membrane, and so into the general system. The theory now generally accepted with regard to the action of salines, is that they are not absorbed, and that they prevent the water with which they are combined from being absorbed; hence the water, by exciting the peristaltic action of the bowel, brings about a movement to discharge it, and with that the other contents of the intestinal tube. There is considerable to lend support to this view. You need not, therefore, give large doses of saline cathartics, as a half-drachm of the sulphate of magnesia, dissolved in a pint of water, commonly operates very nicely.

There is another curious fact which may here be mentioned, namely—the addition of small doses of quinine to salines increases their power of acting upon the intestine. For example:

R. Magnesia sulphas..... ℥i.

Quin. sulph..... gr. i.

mixed and taken in a tumbler of water every morning rarely fails to produce all the laxative effect required, in every form of deficient secretion from the bowels; for instance, in the constipation following fever, when you desire to obtain a free alvine evacuation.

It is well for you to tell the patients that they will not, perhaps, see much effect for one or two weeks, but if they can be induced to persist in the daily use of large quantities of water, a great deal of benefit will almost certainly follow. There is a supposition on the part of the laity that certain fruits are laxative, and that is probably true to a limited extent. *Oranges* may be eaten with benefit, but it usually requires ten or twelve to overcome an obstinate constipation, a fact which renders the remedy quite impracticable in this climate. In the warmer climates, however, the worst forms of constipation which appear can be overcome by oranges alone, and the more juicy they are the better, from the fact that the citric acid which they contain has a tendency to produce a catarrh of the intestine if taken in excess. *Figs* are a rather dangerous laxative, for they may obstruct the intestines: there is not much danger, however, in this direction, if taken with a large quantity of water. It will be found necessary to use about double the amount of water with figs that will be required with any other laxative fruit. The fruits of this climate are very uncertain in their action; the action of apples is very good, but very many persons are unable to take them in sufficient quantity to produce any effect upon the bowels, although they may at the same time take a large quantity of water. All along you will find that water is one of the most important agents to be employed for overcoming deficient secretion in the intestine, attending constipation. If *flatulence*, resulting from decomposition of the intestinal secretion, accompanies the constipation, you may have recourse to the following pill:

R. Assafœtida..... gr. iv.

Saponis..... gr. ix.

M.

To this may be added *nux vomica* if there is evidence of *deficient innervation* in the intestine.

How are you to judge that the leading element in the case is deficient innervation? I am now speaking with more special reference to the small intestine. As a rule, you may say with safety that deficient innervation is an accompaniment of the constipation that troubles persons with sedentary habits of life.

As a rule, it attends the constipation present in elderly persons; and such constipation also occurs among those whose occupation causes them to maintain positions in which the abdominal muscles are to a very great extent motionless, such as shoemakers, tailors, etc., etc. There is also a tendency to headache, and there is a great deficiency in the excretion of the coloring matters of the bile, as might be expected; for the secretory action of the intestines is as much interfered with as is the muscular action. Hence this class of patients are usually of dull sallow color; there is a tendency to greasy accumulations upon the surface; the entire movements are sluggish; and there is usually a lack of frequency in the pulse.

Now, with regard to the treatment for this class of cases.

In the first place, the habits of the patient have a tendency to keep up the constipation, but the means to be employed for overcoming it are quite different from those resorted to in the other class. As a rule, these patients do not bear much water, and why not? Because it weakens their digestive powers, and they will very soon complain of loss of appetite, heaviness in the head, etc.; and it does not excite much peristaltic action in the bowels. At all events it is not nearly so apt to increase the peristaltic action as in the class of cases in which deficiency of secretion in the intestinal canal is the leading element.

What you wish to do here is to arouse the peristaltic action of the bowels, and at the same time increase the general innervation of the secretory apparatus. To do this, the best means that can be employed, if the patient is permitted to remain at his occupation, is water applied externally. The only way in which they can derive benefit from the internal use of water is to send them away from their business to a mineral spring. Then, having a change of occupation, the water taken internally will give them much benefit. But most of your patients will be unable to make this change, and for those water may be used externally with great advantage. Direct that a sitz bath be taken every night, in water as cold as the patient can bear, and have a good reaction afterwards. In a great many cases this simple measure will work wonders, just as it will do in certain cases of deficient innervation of the large intestine.

Another method of using water externally is, on rising in the morning to sponge the spine and bowels with cold salt water, made about as irritant as possible.

In other cases great benefit will be derived by giving the bowels a local shower-bath; and that can be done by dashing the water against the abdomen while the patient is in the standing position. This brings about an action in the bowels the same as a cold hand upon the abdomen causes contraction of the uterus; that is, it is through the sympathy of the nerves of the surface with the viscera underlying them.

In this class of cases *nux vomica* has proven itself a very efficient remedy, and it may be administered in combination with any drug you may wish to use. It will increase the efficacy of small doses of the resinous cathartics, which are irritant and stimulant; hence small doses of rhubarb with *nux vomica* and soap, may

be given in the form of a pill with much more benefit than when administered separately.

The application of the faradic current, one pole of the battery placed over the spine, and the other passed up and down over the abdominal walls, will, in many cases, be found beneficial.

What is known as the health-lift will prove advantageous in certain cases, and the reason is that it brings into action all the abdominal muscles, especially the recti, and that action is brought to bear directly upon the sluggish intestines. When any lesion of the bowels is present, the health-lift cannot be employed.

There is another form of constipation that may be mentioned in this connection, and that is the

#### CONSTIPATION DEPENDENT UPON DIABETES.

In that instance, it is due to total deficiency of secretion into the intestinal tube, and death may result in consequence of the constipation which occurs in connection with that disease.

#### CONSTIPATION DEPENDENT UPON CERTAIN CONDITIONS PRESENT IN THE LARGE INTESTINE.

We come now to the large intestine, and here we find that constipation depends upon nearly the same conditions as were found present in the small intestines. That is, we have constipation dependent upon deficiency of action, and that it in turn may depend upon deficient secretion or deficient innervation, but it is far more commonly dependent upon the latter. Here the patient may be troubled with large fecal accumulations, and that condition may depend upon deficient nerve power on the part of the colon, or the deficient innervation may be confined to the rectum.

One of the worst forms of constipation may occur, dependent upon no other condition than that which is present in the rectum alone, and unless the physician is upon the alert the result may be the development of a rectal abscess.

When this condition is present, the patients have but little knowledge that they should have a movement from the bowels, and whenever the sensation is developed they have little or no power to expel the fecal accumulation. When such symptoms are present it is a pretty certain indication that they depend upon deficient innervation of the rectum, and, unless that condition is overcome, serious consequences may follow. One of the most common causes of this condition is a chronic inflammation set up about hemorrhoids. Prolonged inflammation of any part, especially, however, about the mucous membrane, produces deficient innervation, and then follows a relaxed condition, and with this deficient innervation we are, therefore, very liable to have prolapsus of the rectum.

These patients are peculiar in one respect, namely: they are very generally low-spirited. It sometimes happens that insanity is developed by such a diseased condition of the rectum, and is relieved when the rectal trouble is removed.

With regard to treatment, the first indication is to keep the rectum empty. When fecal accumulations are present, the most efficient and convenient method of removing them is by means of enemata; but just here I wish to say a few words of caution with reference to resorting to that measure. You should never prescribe enemata as a regular treatment, for if the patient gets into the way of emptying the bowels daily in health by enemata, they can never dispense with their use. If you recommend that the patient should use the syringe every morning for the purpose of evacuating the bowels, and it is continued regularly for six weeks, he has gone considerably far toward

making it a necessity during the remainder of his life. Do not abuse the measure if you can possibly avoid doing so. It will probably be necessary to use this means for removing accumulations which happen to be present, but when they are thoroughly cleared out you should at once resort to other measures for restoring lost innervation to the bowel, and one of the very best of these is the local use of strychnia. It is an exceedingly valuable specific in these cases.

It will frequently succeed in curing the worst forms of prolapsus of the rectum, as well as that condition in which there is simple debility with hypertrophy of the mucous membrane. The manner in which you can carry long-standing cases of prolapsus of the rectum by means of injections of strychnia into the submucous tissue itself is sometimes wonderful. If necessary, you can draw a fold of the mucous membrane down and then insert the injection.

I have relied upon this agent almost exclusively in the treatment of this class of cases, whether the real cause was hypertrophy of the mucous membrane from long-standing hemorrhoids, or there was a simple deficiency of power in the rectum to expel its contents. There is another class of cases in which this agent will prove beneficial, and that is cases of prolonged cystitis from any cause. As is well known, elderly men who suffer from enlarged prostate, suffer more or less from cystitis, and they are always apt to have accumulation of fecal matter in the lower part of the bowel, and it is for the reason to which reference has just been made, namely, deficient innervation. Hence in the treatment of any form of cystitis, especially that accompanying enlarged prostate, if the patient complains that the evacuation from the bowels is small and that the movement does not seem to completely empty them, clear them out effectually by means of enemata, and then use injections of strychnia, and you will find that in very many cases both conditions will be materially relieved. With the other form of constipation there is a tendency to the formation of scybalous masses. The most common situation of such accumulations is at the upper part of the rectum, and next in the transverse colon. It is only when they are dislodged that they come down into the sigmoid flexure. It is in these cases that you will find the mineral waters most beneficial of anything that can be employed. In the first place, the mineral water will loosen the scybalous masses without depressing the patient in the least, and it will also prevent new accumulations. Of these the Congress or Kissingen may be used, or both may be used at the same time. In this class of cases you will derive considerable benefit from the use of belladonna or stramonium in the form of a suppository. The patient may take his Kissingen water in the morning, and use a suppository of belladonna or stramonium at night. If the belladonna is employed, it should be given in such quantity as will produce a little dryness of the throat and slight dilatation of the pupil the following morning.

Faradization along the track of the colon is equally beneficial as in the treatment of constipation of the small intestine, and the hip-bath may also be of service, but it does not answer so good a purpose as when the small intestine is chiefly involved. If you can avoid the use of enemata except for the purpose of removing fecal accumulation near the anus, do so, for the effect produced by much over-distention of the intestine is bad.

A single over-distention of the bladder may be followed by a permanent weakness for the remainder of the patient's life, and that distention may not last more than eighteen hours. So a single over-distention

of the intestine may greatly weaken the normal rhythm of that tube.

#### CONSTIPATION AND FECAL ACCUMULATIONS FOLLOWING FEBRILE DISEASES.

The effect of fever is to dry up all the secretions present in the intestine; consequently a very common complication, when a patient is making a recovery from pneumonia or any other disease in which fever has been a leading element, is an accumulation of feces at different parts of the intestinal tube.

In former days, when fevers were treated upon the plan of administering medicines which were to eliminate the poison from the system by way of the bowels, scybalous accumulation did not occur very frequently; but nowadays, when the treatment is conducted upon an entirely different plan, the fever may be continued and retained as the direct result of fecal accumulation. This is especially true of the latter stages of a fever; but such accumulation can be prevented from forming, and be removed by the use of a proper kind of cathartic.

For this purpose there is no combination more serviceable than the compound jalap powder, and it is the one which by all means should be employed. It promotes the discharge of the serous elements into the intestine, assists in the absorption of the deposits which have taken place in the lung, if the case be one of pneumonia; also acts upon the kidneys as well as the bowels, and is one of the mildest that can be employed which so fully meets the indications in this class of cases.

## Original Communications.

### SOME POINTS RESPECTING DIPHTHERIA.

By BENJAMIN EDSON, M.D.,

BROOKLYN, N. Y.

THE idea is fast gaining ground that diphtheria, when not communicated from person to person, is generally, if not always, due to unsanitary local conditions. It may be developed from foul, stagnant water, from defective drainage-pipes, permitting soil-saturation with the unwholesome fluids that should be conducted safely away, or, as is too frequently the case, from cheap and defective plumbing, without proper traps and devices for preventing the intrusion of noxious sewer-gas into the sleeping apartments and living-rooms of dwellings.

So long as there continues to be danger from these causes, so long there rests upon every one the duty of contributing, so far as he may, any facts and observations bearing upon this subject, which may aid in bringing home to all a conviction of the danger which threatens so many households.

This is my apology, if any be needed, for detailing the particulars of twelve cases of this disease occurring in the Home for Destitute Children in this city, in the latter part of December, 1876, and the early days of January, 1877. Part of them I observed in the service of Dr. Wm. H. B. Pratt, and part of them were under my own immediate care.

In the "Home" are over one hundred children from two to twelve years of age, and of about the average class found in such public institutions.

Many of them inherit feeble and tainted constitu-

tions—some are the offspring of dissolute parents—others are orphans with more or less tendency to diseases from which their parents have died.

The "Home" is a model of cleanliness, and is in all respects admirably kept, no pains being spared to in every way conduce to the comfort of those entrusted to its care.

It was then a matter of no little surprise, when, in December last, a case of diphtheria was brought to the notice of the attending physician. The building was at once carefully inspected—as it was then thought—but no unsanitary condition could be discovered. Other cases followed in quick succession, and as new cases were developed, the plumbers again and again examined the building, and declare that there was nothing wrong about it—that everything was in perfect order. Every child affected was promptly removed to the hospital of the institution.

The greater part of the children affected by the disease were from two to five years of age—innates of the nursery on the first floor. This nursery consisted of three adjoining rooms, separated by wide folding doors, which were usually kept open. The three rooms were occupied in common as living and play rooms during the day, and the two extreme ones, the doors still open, were used as sleeping-rooms at night. In this nursery there were twenty-seven children.

In course of the repeated searches for the hidden cause of the epidemic, it was eventually noticed that all the cases from the nursery were of children that slept in one room, and that the room apparently least exposed to unsanitary influences. This discovery was followed by still more searching examination, which revealed what had been hitherto unsuspected, that the soil-pipe from the water-closet on the third floor crossed the building on a line adjacent to some of the dormitories, then turning at an angle downward passed to the sewer, and in its course was encased in the wall of this affected room. It was then further ascertained that a room directly over the nursery formerly had a wash-basin communicating with this main pipe, and there was a tradition that at times the room was so filled with sewer-gas that the occupants were forced to leave it.

Still further, a small part of this same affected room was found to have been formerly a water-closet. The partitions and appurtenances having been removed, and the space included in the nursery, the soil-pipe was merely levelled below the floor, and more or less effectually plastered up.

From these pipes the sewer-gas had no means of escape, except through defects in the plumbing into the occupied rooms. So insidious had this been that it had escaped particular notice.

To relieve this condition of things, a shaft was extended from the vertical portion of the pipe directly upward through the roof, thus affording a free escape for the ascending sewer-gas into the open air.

This was done on the 6th of January. On the 7th the last case of diphtheria was sent to the hospital, the child presumably having received the poison into his system before the alteration was made.

Up to this time there were three or four new cases each week; since that time not a single case has occurred in the institution. A brief summary of the points thus far embraces: The development of diphtheria; its continuance; the suspected cause; finally, its removal, followed by the immediate and absolute subsidence of the disease.

The special point of this history is its *completeness*, coming so near to positive proof that there is little left to be supplemented by inference.

In view of recent discussions respecting the diagnosis of croup and diphtheria, it may not be out of place to refer to these cases somewhat in detail. I do not think that this part of their history is calculated to shed much light upon disputed points; indeed, they have rather served to unsettle some very fixed opinions that I previously held.

Of the twelve children attacked three died. Of these three, two were clearly diphtheritic from the first, the disease subsequently extending to or developing itself in the larynx. The third case was one of pseudo-membranous laryngitis from the first, the pharynx at no time being affected.

One child that died had twice had pneumonia; his mother died from phthisis, and he had lost an eye from a previous attack of measles.

Eight of the cases were beyond question cases of diphtheria. The remaining four had been considered sporadically, would unquestionably have been considered typical cases of true croup, being clearly laryngeal throughout their entire history. Occurring, however, as they did in close succession—due, beyond question, to the same local cause—it was deemed warrantable, if not absolutely correct, to consider them all cases of diphtheria. It has been said by those considered to be good authority that we cannot be sure in our diagnosis of diphtheria until the membrane is visible in the fauces. I am not prepared to take issue upon this point; but in these four particular cases I find it easier to believe that they were diphtheritic, due to the poison of the sewer-gas, than that they were only cases of croup, "sporadic," or merely the result of "a cold," or that we had in this instance an epidemic of croup.

In conclusion, it is but justice to myself to say that, while from the carefully chosen language of theorists and writers it seems very easy to reach the conclusion that croup and diphtheria are two distinct diseases, due to very different causes, and readily distinguishable—an opinion that I have tried hard to maintain, and am still very unwilling to abandon—a careful study of a group of cases such as I have briefly referred to leaves me with convictions somewhat unsettled upon several of the disputed points.

In my present condition I deem it prudent to wait for further light on this subject.

140 PARK PLACE, BROOKLYN.

## CRESOTINIC ACID IN ACUTE ARTICULAR RHEUMATISM.

By GEO. M. EDEBOHLS, M.D.,

HOUSE PHYSICIAN, ST. FRANCIS' HOSPITAL, N. Y.

THE *Berliner klinische Wochenschrift* of July 31, 1876, contains an article on the antipyretic effects of cresotinic acid, by Dr. C. E. Buss, of Basel. Amongst others, a brief allusion is made to two cases of acute articular rheumatism, in which sodium cresotinate was administered with the most happy results. The perusal of this article prompted Dr. Carl H. Lellmann to a trial of the remedy, and the results, so far as obtained, are herewith presented to the profession. Only two ounces of cresotinic acid could be procured in this city. This was exhausted in the treatment of the two cases narrated below, and a stop thereby put to further experimentation at present. The drug has, however, been ordered in larger quantities, and on its arrival it is proposed to continue the investigation of its therapeutic effects.

Cresotinic acid,  $C_7H_5O_2$ , is derived from cresol, and is obtained by introducing carbon dioxide to sodium

eresylate. It occurs in fine, white, prismatic crystals, soluble with difficulty in cold water, but readily soluble in hot water, alcohol, and ether. Its taste and action on mucous membranes are almost identical with those of salicylic acid. Sodium cresotinate is very soluble in both hot and cold water, entirely unirritating, and neither in substance nor in concentrated solution productive of any perceptible changes on the mucous membrane. For these reasons it was decided to employ the salt in preference to the acid.

**CASE I.**—Wm. Weber, æt. twenty-four; cabinet-maker. Admitted to St. Francis Hospital, service of Dr. Lellmann, March 11, 1877. One year ago had an attack of acute articular rheumatism which lasted four weeks. The present attack began on March 4th, six days before admission. The ankles were first affected; subsequently the right knee, right elbow, and both wrists. On examination at eight P.M. of day of admission both wrists and the right knee were found hot, swollen, red, and tender; the right knee was moderately distended by an accumulation of fluid in the synovial cavity. The patient was suffering intensely, tongue thickly coated, pulse 116, temperature  $102\frac{1}{2}$ ° F. Ordered: R. Acid cresotinicæ, sodii bicarbonat., ãã gm. 8.0; syrup aurantii cortic., gm. 15.0; aquæ gm. 165.0. M. Tablespoonful every two hours.

March 12, 11 A.M.—Patient had taken one table-spoonful of the medicine last night, and two this morning, altogether gm. 2.0 of cresotinic acid. Wrists and right knee present the same objective symptoms as yesterday; pain, however, is very slight, and distention of knee-joint less. I administered gm. 2.66 of cresotinic acid at one dose. At two P.M. the patient is entirely free from suffering; the knee scarcely shows a trace of inflammation, and is absolutely painless; the wrists, though still hot, red, and swollen, can be freely moved without causing the slightest pain; pulse 92, temperature  $101\frac{1}{2}$ ° F.

March 13, 11 A.M.—Has taken gm. 8.0 cresotinic acid since yesterday—gm. 12.66 in all since treatment was begun. All signs of local inflammation have disappeared; there is no pain anywhere. Pulse 78; temperature in rectum  $99\frac{1}{2}$ ° F.; skin moist; tongue still slightly furred.

March 14, 11 A.M.—Taken gm. 3.33 acid cresotinic since yesterday morning—gm. 16.0 in all since beginning of treatment. No local or general symptoms of the disease present; pulse 66; temperature  $98\frac{3}{4}$ ° F. All treatment discontinued.

March 15, 11 A.M.—Pulse 54; temperature  $98\frac{3}{4}$ ° F.

March 16, 11 A.M.—Pulse 50; temperature,  $98\frac{1}{2}$ ° F.

The temperature remained normal during the remainder of the patient's stay in hospital. The pulse on the 17th was still only 50; from that time it gradually rose, and on the 19th reached 66, the patient's normal pulse. Discharged March 31st, having had no disagreeable symptom, and no treatment since the 14th.

**CASE II.**—Occurred in the private practice of Dr. Lellmann, to whose kindness I am indebted for the details. A. H., male, æt. forty-eight, was taken with acute articular rheumatism, March 15, 1877. It was his second attack, the first having occurred fifteen months previously, and lasted two weeks. The knees were principally affected, and an unusually large amount of effusion had taken place into both joints, causing the most intense suffering. After taking gm. 10.0 cresotinic acid, in combination with sodium carbonate, per diem, for two days, the joints were perfectly painless on either pressure or motion, although the heat and swelling still remained. Gm. 8.0 more were taken during the third day, when symptoms

similar to those of salicylicism supervened—dull headache, tinnitus aurium, and free perspiration, with a general feeling of malaise. At the same time all symptoms due to the rheumatic affection had entirely disappeared, and the medicine was at once discontinued. During the first day of its administration the patient noticed a marked increase in the quantity of the urinary secretion, which was clear and of a bright yellow color. By subsequent measurement it was ascertained that from two hundred and twenty to two hundred and forty fluid ounces per diem were passed during the following three days.

The influence of cresotinic acid on the temperature in Case I. was quite marked, and harmonizes with the results obtained by Buss, who considers it fully equal in antipyretic powers to salicylic acid and quinine. In Case II. no temperature record available for satisfactory deductions could be obtained.

The reduction of the pulse rate was still more noteworthy, and corresponds very closely to the same effect habitually observed during the administration of salicylic acid. In Case I. the pulse rapidly fell to below the normal, and remained thus for three days after the acid was entirely discontinued. In Case II. there was a fall from 90 to 70 per minute during the first twenty-four hours; during the remainder of the time the patient was under observation the pulse varied between 60 and 70.

But the most striking feature of the progress of both cases was the complete cessation of pain in the affected joints, while they still presented all the objective signs of acute inflammation. In this condition all the different movements of which the respective joints were normally capable could be undertaken without the slightest inconvenience.

A very marked diuretic effect was observed in Case II., and the disagreeable symptoms which arose on the third day point to the propriety of carefully watching the effects of the remedy.

## Reports of Hospitals.

### PRESBYTERIAN HOSPITAL, N. Y.

#### FRAGMENT OF RIB IN THE PERINEUM.

(Reported by W. F. FOREST, M.D.)

OWEN McCABE, aged 64, out-patient. While the patient was straining at stool, he felt something come down which he supposed to be a hæmorrhoid. A sharp pain succeeded, and continued day and night. Three days later, a large abscess appeared between the coccyx and anus, a little to the left side, and opened spontaneously. On the tenth day from the time of the attack he was first visited, and was then too sick to be moved to the hospital. He was suffering from septicæmia; had had three chills during the day, followed by profuse sweating, and was in an alarming condition.

Two large abscesses in the perineum were found and opened, and the patient was put upon a treatment of quinia sulph. grs. v., and ferri mur. tr. gtt. xx., every two hours, with milk, eggs, and brandy *ad libitum*.

Bare bone was detected in the vicinity of the coccyx, which was thought to be the coccyx dissected out by the abscess. When the patient had rallied from his hectic, this dead bone was removed and found to be a piece of a rib. This fragment was  $1\frac{1}{2}$  inches in length,  $\frac{3}{8}$  inches in breadth, very sharp at one end, rounded

at the other, and evidently broken out from the body of a rib. It resembled a portion of one of the lower ribs of the human skeleton. In trying to account for the presence of this piece of rib in the perineum, it was thought at first that the patient must have swallowed it. But this the patient indignantly denied, and, indeed, it would seem impossible that such a sharp piece of bone could pass through the more than 25 feet of the alimentary canal without causing serious trouble. No evidence of a fistula leading into the intestine could be discovered.

On questioning the patient very closely as to an injury, it was found that three years previously, he had been injured about the head and shoulders by a floor falling upon him, but he had no suspicion that a rib had been broken at that time; has had no injury, and has been a perfectly well man ever since. He was examined, and along the body of the tenth rib of the right side an irregularity was detected, as if a fragment might have been broken out of its body.

From these considerations it was thought that this piece of rib,  $1\frac{1}{2}$  inches in length, had been broken out from the tenth rib of the right side, remained in the body three years, travelled across the body from the right to the left side, and down into the perineum, and during this time had not caused a single symptom, or produced any trouble until it reached the perineum.

#### DIABETES INSIPIDUS.

This was the case of a boy 8 years of age. He has had the disease for the last two years. No history of an injury to the head, or any known cause for the disease. His father was said to have had the disease when he was two years of age, but recovered fully.

The patient is a bright, intelligent, active boy, and does not differ in appearance from other boys of his age, except that he is small for his age and has an unusually large head. He has lost but little flesh during the last two years, but has not grown any in size during the time.

His urine was examined and found to be of a sp. gr. of 1000.1, nothing abnormal in it, and in appearance resembled Croton water. The amount passed in 24 hours varied from 150 to 218 ounces, nearly  $\frac{1}{3}$  of the boy's weight.

The patient was permitted to drink all he wished, and the amount was carefully observed. It was found that during 24 hours he drank 80 ounces of fluid, including in this water, milk, and coffee, and during the same period he passed 218 ounces by the kidneys, nearly three times as much fluid as he drank.

These observations differ from those of Niemeyer, who claims that the amount of urine excreted in these cases can never exceed the quantity of fluid imbibed, without the occurrence of a corresponding decrease in the weight of the body.

The boy was taken from the hospital before many observations could be made, and before a plan of treatment could be carried out. The plan of treatment to have been tried was to act upon the skin energetically by hot air-baths and other diaphoretics, in hopes that, by diverting the excretion of water from the kidneys to the skin for some time, a permanent change in the action of the kidneys might be reduced.

#### PURULENT PERICARDITIS AND PNEUMONIA.

R. E. R., aged 21, adm. Feb. 15th. Family history good. Patient had acute articular rheumatism three years ago. Been in ordinary health since then until six weeks ago, when he began feeling unwell with slight chills, and after two weeks of malaise, he de-

veloped acute articular rheumatism again. Treated with salicylate of soda, and in a few days the pain and swelling left the joints. Two weeks ago his physician informed him that he had pneumonia. He had had no chill or cough, or any symptoms of an attack of pneumonia. He was examined on admission, and found dulness on percussion, with bronchophony, broncho-vesicular respiration, and subcrepitant râles heard over the lower lobes of both lungs on auscultation. The dulness over the lower lobe of right lung approached flatness. Diagnosed as a case of double pneumonia, and put upon usual treatment.

On auscultating the heart, a slight friction sound was heard, an aortic obstructive murmur, and the heart was found to be enlarged.

The exaggerated respiratory murmurs disguised the heart sounds very much.

For the first four days the temperature of the patient remained low, and he steadily improved. On the evening of the 19th, the patient's temperature, without any ascertainable cause, suddenly went up to  $103\frac{1}{2}^{\circ}$ ; pulse, 120. During the next day, temperature remained at  $103\frac{1}{2}^{\circ}$ ; some dyspnoea. In the evening, temperature,  $105^{\circ}$ ; pulse, 135; respirations, 40. Quinine and digitalis had had no influence on the temperature and pulse thus far. The next morning, the 21st, temperature,  $105\frac{1}{2}^{\circ}$ ; respirations, 45; marked dyspnoea; heart beating in a *very irregular, rapid, and tumultuous manner*; pulse could not be counted.

Complained of pain in the precordial region. Two leeches were placed over the apex of the heart, and 25 grains of quinine administered. In twenty minutes the heart was beating regularly; pulse, 120—full, and regular. In one hour from the time of applying the leeches and giving the quinine, the temperature had fallen from  $105\frac{1}{2}^{\circ}$  to  $101\frac{1}{2}^{\circ}$ ; pulse, 120; respirations, 26.

The temperature did not rise again above 102, and he appeared quite comfortable. In the evening he was delirious, and raised himself in bed in spite of the efforts of an attendant. Immediately he fell back and expired.

*Autopsy.*—Right pleural cavity contained eighteen ounces of clear serum. The lower lobe of right lung was consolidated, partly by circumscribed pneumonia, and around this hepatized lung. Lower lobe of left lung was consolidated completely, but apparently not by pneumonia. It had a brownish-red, mottled appearance, such as is caused by long-continued congestion.

Heart and pericardium together weighed forty ounces. The pericardium was greatly thickened, in some places being one-fourth of an inch in thickness, and attached in many places to the heart. On opening the pericardium, about two ounces of thick yellow pus ran out. The external muscular layers of the heart were all dissected out, in some places to the depth of one-fourth of an inch, so that the heart had a remarkable shredded appearance.

The cavities of both ventricles very much enlarged, and the walls of the left ventricle greatly hypertrophied. The walls of both ventricles were in a state of fatty degeneration, the muscular tissue having a soft, gelatinous appearance. Small vegetations on aortic valves. Liver enlarged, and contained evidences of congestion.

Evidences of congestion in the other abdominal regions.

Some of the points of interest in this case would seem to be these:

*First.*—A case of purulent pericarditis associated with articular rheumatism and pneumonia. Purulent

pericarditis is rare, except as secondary to septicaemia, or puerperal fever, etc.

*Second.*—The presence of all the physical signs of pneumonia in both lungs, and yet the post-mortem revealing typical pneumonia in but one lung; the intense congestion giving rise to hepatization of the lungs.

*Third.*—The very extensive heart lesion that existed without giving rise to symptoms that pointed particularly to that organ, until a short time before death.

*Fourth.*—A heart that has been diseased and hypertrophied of old would seem especially liable to undergo degeneration when a disease sets in accompanied by a high temperature, as in pneumonia, or typhoid fever. Thus a former rheumatism may influence the prognosis, and indicate special efforts to control high temperature in a subsequent acute disease.

*Fifth.*—The soothing influence on the heart of local blood-letting. On the morning of the 21st, his temperature was  $105\frac{1}{2}^{\circ}$ ; respirations, 45; heart beating so rapidly and tumultuously that pulse could not be counted. About one-half ounce of blood was drawn by two leeches placed over the region of the heart, and in a few minutes the pulse was 120 per minute—full and regular; dyspnoea and pain gone. This result came about too quickly to be due to the quinine administered.

The soothing influence of local blood-letting we have seen manifested in other diseases. In a case of acute pleurisy, where the temperature was  $105^{\circ}$ , the pain excruciating, and only partially relieved by opium, the application of a single leech over the painful side relieved the pain almost instantly, and for a very long time. The same relief from the application of a leech is obtained in the pain of pneumonia.

*Cerebral Congestion and Local Blood-Letting.*—The influence of local blood-letting on the cerebral circulation was manifested in a case of cerebral congestion. The patient had softening of the brain from atheroma of cerebral arteries, and clot in the middle cerebral. Cerebral congestion set in suddenly one evening. The temperature ran up to  $105\frac{1}{2}$ ; pulse, 140; respirations, 52 per minute; pupils dilated; breathing stertorous; face scarlet—in short, the symptoms of dangerous cerebral congestion. Leeches were placed behind the ears, and an ice cap to the head. No other treatment was employed. The symptoms abated at once, and in thirty minutes the temperature fell to  $102^{\circ}$ ; pulse, 115; respirations, 30 per minute. After a few hours the patient was in his usual condition.

*Treatment of Facial Neuralgias.*—In the treatment of facial neuralgias, migraine, and sick headaches, we have found nothing so satisfactory as croton chloral. We have tried the usual remedies—gelsemium, morphine, blisters, etc.—but with indifferent success. Lately we have used the croton chloral, as recommended in the *Lancet* and *Practitioner*, and with excellent results. The croton chloral is given in solution with elixir calisaya; five grains three times per day for a week. When taken in this manner the habit of the neuralgia is broken up, and a permanent cure frequently results.

**DIAGNOSIS OF PARALYSIS OF THE MUSCLES OF THE FOREARM.**—To distinguish saturnine paralysis from paralysis produced by an affection of the radial nerve, M. Hardy points out one characteristic sign. In radial paralysis the *supinator muscles* are affected as well as the *extensors*, while in lead paralysis the extensors only are affected, and this explains why the patient can carry the head supine.—*Med. Press and Circular.*

## Progress of Medical Science.

**RECURRING CHANCERE OF THE PENIS FOLLOWED BY EPITHELIOMA.**—On Dec. 13, a man, aged 65, was admitted into King's College Hospital, with the following history: Seven years before, he contracted a chancre, which was followed in a month by a secondary rash on the skin, sore throat, and "cramps" in the legs, which were worse at night. The chancre gradually healed, but twelve months afterwards it reappeared in its old site after a drinking-bout. It healed up again within three weeks. After that date the chancre recurred four or five times. The patient stated distinctly that the reappearance had always been preceded by drinking-bouts, and that it had never been due to any fresh sexual connection. The chancre always disappeared again within a month. The secondary rash also reappeared four or five times, but not necessarily coincidentally with the chancre. No family history of cancer was obtainable. Six weeks before admission, a sore appeared in the usual site. Instead, however, of healing up at the usual time, it had spread; it had also been the seat of very severe pain, a symptom which had not been present previously.

On admission, dark-brown stains were found scattered over the chest and abdomen. The left half of the glans penis was extremely hard throughout. On the surface it presented an irregular, eroded, and slightly nodulated ulcer, the base of which was extremely hard and covered in parts with a greenish slough. The edges were raised, everted, and slightly nodular. There was very little discharge. The hardness extended backwards and involved the anterior half of the penis, gradually diffusing into the normal tissue. The part was very painful and tender on pressure. Along the root of the penis there was an irregular, interrupted, and painful cord of hardness. The glands in the groin were hard and lobulated, and a few seemed of larger size than those usually met with in syphilis. The patient was thin and cachectic. Amputation of the penis was proposed, but the patient would not consent to it.

In connection with the above case, the following case of epithelioma following buccal psoriasis is of interest: The patient, a man 45 years of age, had suffered for five or six years from a tumor of the vault of the palate. At the outbreak of the malady, the lesion consisted of a small crack, a sort of erosion, and at the same time the patient discovered the existence of a white, rather thick skin, covering the whole of the inferior face of the soft palate. He had smoked a pipe for twenty years, and for fifteen years had been affected with buccal psoriasis. When admitted to the *hôpital des cliniques*, the whole of the palatine mucous membrane on the right side was replaced by a red, flabby, fungous mass, which terminated a little in front of the great molar. It also extended a little over on the left side. In the median line there was a small fistulous opening into the nasal fosse. The tumor was not painful, but interfered somewhat with deglutition. A little below the angle of the jaw there was a swollen gland, a little larger than a hazel-nut. The tumor had latterly grown rapidly, and the patient had become a good deal emaciated. As anti-syphilitic treatment proved useless, Mr. Broca performed resection of the superior maxilla on Nov. 27, 1876. All the diseased parts were removed, but the soft palate was left intact. The microscopical examination of the tumor showed that it belonged to the class of tubular epitheliomata. The bony lesion at the site of the fistula consisted in a simple suppurative osteiti.

The mucous membrane covering the floor of the nasal fosse was thickened, infiltrated, and vascular, but did not contain epithelial proliferations like those found on the vault of the palate.—*The Lancet*, March 10th, and *Le Progrès Médical*, Feb. 17, 1877.

**A VASO-MOTOR NECROSIS IN HYSTERIA.**—Dr. Armaingaud recently had under treatment a hysterical patient, suffering from cervico-brachial neuralgia attended by convulsive attacks, in whom these symptoms were replaced by attacks of sopor, which gradually became regular, and alternated with other phenomena. For example:

1. A first attack of sopor would come on at a quarter to eleven in the morning, and last a quarter of an hour.
2. At a quarter to two a second attack of sopor would come on, lasting an hour and thirty-five minutes.
3. At half-past five a local congestion of both eyes would appear, and continue for two hours.
4. A local asphyria of the extremities would set in during the congestion of the eyes, and disappear a few hours after it.
5. At five minutes past six a very severe attack of intercostal neuralgia on the right side would commence, and cease abruptly at half-past six precisely. This last symptom did not make its appearance until fifteen days after the cure of the cervico-brachial neuralgia. Finally, towards the end of the malady, a chromhidrosis of the eyelids was added to all the other phenomena.

During the attacks of sopor there was absolute insensibility of all parts of the body, except over a single spinous process, that of the second dorsal vertebra. Pressure over this point caused most intense pain. Strange to say, all the above phenomena disappeared after the application of blisters, followed by the continuous current to this point. The chromhidrosis alone persisted.—*La Tribune Médicale*, Feb. 4, 1877.

**THE SUBSTITUTES FOR QUININE.**—In view of the present high price of quinine, the febrifuge *par excellence*, it may be well to remind our readers that the other and cheaper alkaloids of cinchona possess the same properties almost in an equal degree. Since 1866 the government of India has appointed several commissions to examine the therapeutic values of the different alkaloids extracted from the cinchona bark. Of 1,145 patients treated:

410	took cinchonine,	and 400	were cured,
359	“ cinchonidia,	“ 346	“
376	“ quinidia,	“ 365	“

or in all 1,111 were cured. From these facts the commissioners at Madras concluded that the effects of the three alkaloids differed little from those of quinine, for which they can be readily substituted. Cinchonine and cinchonidia can be manufactured for one-third the price of quinine. Cinchonidia is said to agree better with some stomachs than quinine; it is also said that it does not cause cinchonism, but this is an exaggeration. In general, however, it does not cause this unpleasant symptom unless the dose be considerably above the average dose of 5 or 6 grains.—*Lyon Médical*, February 25th.

**A NEW THEORY OF THE ORIGIN OF TYPHOID FEVER.**—Three years ago Dr. Stewart, of Barnsley, attended seven or eight cases of this disease in a row of cottages situated on a hill. He traced the outbreak to the decomposition of the blood from a slaughter-house in the row; the blood was allowed to flow into the common sewer, where it remained and putrefied. The waste-pipes from the sinks in the cottages were directly connected with this drain, without the intervention of any kind of trap, and the smell therefrom was often horrible. M. V. Feltz has found by experi-

ments that putrid blood, when dried, mixed with distilled water, and injected into the veins of dogs, causes symptoms very analogous to those of typhoid fever. These symptoms were produced even when all trace of bacterial life had disappeared from the blood injected. While pondering over the above cases, Dr. Stewart's thoughts were directed to the analogies which exist between the symptoms of typhoid fever and those of certain cases of puerperal fever, which appear to arise from the introduction of the products of decomposing blood into the system through the lymphatics or veins of the uterus. Some of these cases have resembled ordinary typhoid fever of a severe type so closely that, if it were possible to have overlooked the puerperal condition, they might have been set down as cases of that fever. The local affections of the genital organs in puerperal fever seem to have obscured the true nature of these cases, by diverting attention from the ultimate general effects upon the system, and concentrating it too exclusively on the local expression of the infection. He thinks that the different channels by which the poison is admitted to the blood—in the puerperal case, by the lymphatics or veins of the uterus, in the typhoid case, by the stomach or lungs—would go far to account for any apparent variations in the symptoms. The poison, too, in the former case, is introduced in a recent and active form, in the latter, usually only after it has lain for a considerable time in the ground, and been washed or percolated into the wells.

A vast number of typhoid fever cases, however, appear to arise from the pollution of drinking water by the excrement of human beings. Now, Dr. Stewart thinks that if we settle upon the serum of the blood as the essential factor of the poison, it will be at once evident how any severe case of diarrhoea would be sufficient to produce the disease, because the liquid evacuations of severe diarrhoea is principally composed of serum of the blood, which is then placed under conditions highly favorable to the development of the putrefactive process. If both decomposing blood and the decomposing liquid evacuations of diarrhoea be capable of causing typhoid fever, then serum of the blood, which is the only component common to both, must be the poison factor. Dr. Low recently published several cases, which prove that the disease may arise from the inhalation of the emanations from fetid stools and privies. This theory of typhoid fever arising from the decomposition of the serous evacuations of severe diarrhoea accounts for the extraordinary prevalence of the fever in the months of October, November, and December, in a more satisfactory manner than any other theory. In consequence of the great prevalence of summer cholera in July and August, abundant material is furnished for the elaboration of the poison, which afterwards percolates into the wells, or is washed by the autumnal rains into the sources of the water supply. Two or three months are probably necessary for this preparation.

Dr. Stewart does not enter into a discussion as to whether the disease can have an abiogenetic origin, though the facts on which his theory is founded seem to favor that doctrine. The questions whether the fever can only arise from specific typhoid germs, which are nearly omnipresent, and may remain dormant for years only to spring into active life when introduced into a proper nidus for their development; or whether the poison may be developed from the ordinary germs existing in all decomposing animal fluids, or is elaborated by some subtle chemical change in the properties of the fluid itself, are, in his opinion, of little practical importance.—*British Medical Journal*, March 10, 1877.

# THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

W.M. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, May 5, 1877.

## THE MEDICAL PROVIDENT SYSTEM.

WE can hardly believe that the Medical Provident System will become popular in this country. Any objections which may be urged against it do not refer so much to the system itself as to the gross abuses to which it must be liable. If the operations of the scheme could be restricted to the channel in which they could do good, no adjectives would be strong enough to express commendation of the efforts of the initiators of this so-called reform. But the question we are to ask ourselves here is, do not the difficulties in the way of making the working of the plan perfect more than counterbalance the ultimate benefits to be obtained?

We start out with the assumption that a perfect Medical Provident System is desirable. We believe no one is ready to question this. What we must understand as a perfect provident system is one which limits its benefits to the really deserving, viz., to that class of respectable poor who cannot afford to pay the usual fees, and yet who do not wish to be paupers. All others should be excluded. How this is to be done is the principal question of the hour. Under the existing abuses of the free dispensary system we have very little hope that this question can be satisfactorily answered. We believe that the great majority of those who would be entitled to the benefits of the provident plan have long since been demoralized by free treatment they have received in these and kindred institutions. What would have been easy to prevent in years gone by we shall now find most difficult to cure. As the dispensaries are to blame for these abuses of medical charity the advocates of the provident scheme have a right to expect aid and countenance from their necessary efforts at reform. In fact, without the assistance of the free dispensaries, they can do absolutely nothing. The free dispensaries, by concerted action, have it in their power to restrict their benefits

to the really poor. Their charters make the exercise of such prerogative a duty rather than a privilege. But have they done it? The question is sufficiently answered by the grossest abuses of medical charity. Are these institutions likely to do better in future? Is there a reasonable chance that more discrimination will be exercised in the treatment of cases? Judging from the past we have nothing to expect for the future.

If, however, the dispensaries choose to exercise their powers, a legitimate and hopeful starting-point will be made for the provident plan. If there is to be any promise of success for the latter it must be grafted on the present dispensary system, but, as before remarked, we by no means believe that this is even probable. And, even if it were otherwise, all good intentions would be frustrated by the college clinics, but more especially by the out-door department of the New York Hospital, where, for a dollar a month, anybody, rich or poor, can be treated without question or hindrance. It would be almost a joke for the provident dispensary men to ask the governors of the New York Hospital to aid in correcting the abuses of medical charity. If the opponents of the provident plan were in need of an example to prove the dreadful abuses to which it may be liable, they could find no more striking one than that afforded by the shameful management of this out-door department.

It is perhaps fortunate that special attention has been invited to such a system of professional jobbery as that inaugurated by the New York Hospital Dispensary just at the time when the provident plan is brought up for discussion. If it prepares the professional mind to look upon all such reforms with suspicion the result is no more than could have been anticipated. Every thoughtful man, however much he may believe in the theory, will have certain very strong misgivings before he is willing to place the theory to a practical test. The present abuses of our dispensary system are bad enough, but we shall certainly make matters worse if, in our attempts at reform, we add to our burdens those of a defective provident plan. Under existing circumstances we certainly run a great risk. What the New York Hospital has done may be done by other dispensaries, and, instead of checking pauperism, may actually place a premium upon it by making it respectable. We believe that the longer the profession deliberate over the chance of success of the new scheme the less they will be prejudiced in its favor. The suggestions offered in another column by Dr. Hanks strike at the root of the present evil, and if heeded may be the groundwork for better management. They certainly tend to correct the more flagrant abuses of dispensary practice, and after all, is it not best to put all our efforts in this direction, that we may properly prepare ourselves for the inauguration of more radical reforms? But we shall have more to say on this subject hereafter.

## SCHOOL HEALTH BILL.

THE School Health Bill is making good progress, and if the Assembly Committee will report upon it in a reasonable time, there can be no doubt that the House will be prepared to act upon it at once. We have so often spoken of the importance of the measure, that it seems hardly necessary to refer to it again, except to urge its passage during the present session. The medical members of the House are well aware of the arguments which have been used in its favor, and such arguments only need be presented to the committee to carry with them conviction. Speaking in the name of the profession for the school-children, the time has come to demand the passage of such a law rather than ask for it as a legislative favor. It is a question of ordinary justice to the school-children, and must now be viewed as such. We have no doubt, however, from what we can learn, that the Assembly Committee will not be derelict in their duty. The prompt passage of the bill through the Senate augurs well for its reception in the Assembly. We would especially call the attention of Dr. Isaac Hayes to this subject, with the hope that he, as the medical representative of this city, will press the matter to its final issue.

## Reviews and Notices of Books.

THE TONIC TREATMENT OF SYPHILIS. By E. L. KEYES, M.D. New York: D. Appleton & Co. 1877.

THIS work is an amplification of an article written some time ago by the author, in which he gave the results of his examinations of syphilitic blood. As is well known, the blood in the most varied diseases has latterly been examined in France by means of an instrument called the *hématicmètre*, by which the quantity of the corpuscles can be quite accurately counted. Wilbouchewitch, in Paris, was the first to examine syphilitic blood by this means, and from his results he concluded that, in small doses, mercury increased the quantity of the red corpuscles, and was, in fact, a tonic. It was well known, particularly by the results obtained by Liégeois, that mercury increased the weight of the person taking it, and the drug has long been known by many to be, in some cases, of tonic effect. These experiments, then, in some measure explain why this increase of nutrition occurs, though to our mind the fact that, upon mercury being given, the red corpuscles are increased in quantity is a very bare one, and simply a statement of cause and effect, without any attempt at explaining the intervening processes, or rather the *modus operandi*. The gist of this book is, that mercury is a tonic in syphilis, hence it must be given. To our mind this explanation of the action of mercury is, as we have said, very unsatisfactory indeed, because we believe that its action is other and different from that of a tonic; otherwise why do not our most powerful tonics cure syphilis? If mercury increases the quantity of red corpuscles in syphilis and cures it, is its action simply and wholly that stated, or is there nothing beyond this? Perhaps, if experiments are made with iron and quinine singly or combined, the same result will follow, but we all know what dismal failures these drugs produce in the

treatment of syphilis, yet they are our most reliable tonics. There is something so convincing in practical demonstration in medicine, that when it occurs we are, we fear, too apt to magnify the importance of the results gained, and in consequence to lose sight of less clearly demonstrated facts which are really important.

There is something of this kind in the present publication. We do not wish to disparage Dr. Keyes's labors and results when we say that we think that the latter are far from being satisfactory, not complete, and that they are simply fragmentary. We already knew that in small doses mercury acts as a tonic and improves nutrition. All of the various cells of the tissues undoubtedly increase in quantity, as seen particularly in the increased development of adipose tissue, and muscular tissue perhaps likewise is increased as to its cell elements in the same category, and as part and parcel of the same process the blood-cells are also increased; and this results whether the tonic be mercury, iron, quinine, or fresh air. As an explanation, then, of the action of mercury that it is a tonic and increases the blood-cells, is no explanation whatever of its action in syphilis, but simply a pleasing practical demonstration of one and perhaps the minor part played by mercury in the whole process. Dr. Keyes very properly advises the long-continued use of mercury, and it is well known that the most experienced men in the treatment of syphilis hold this view, first clearly put forward by Fournier. Besides the subject-matter proper of the action of mercury, the directions are given for the treatment of the various lesions of syphilis.

THE MICROSCOPIST: A Manual of Microscopy and Compendium of the Microscopic Sciences, Micro-mineralogy, Micro-chemistry, Biology, Histology, and Pathological Histology. Third Edition. Rewritten and greatly enlarged. With two hundred and five illustrations. By J. H. WYTHE, A.M., M.D., Professor of Microscopy and Biology in the Medical College of the Pacific, San Francisco. Philadelphia: Lindsay & Blakiston, 1877.

THE Author has aimed in this volume "to place within the reach of the student of nature a compendium of microscopy, free from unnecessary verbiage, which should aid in every department of natural science." In the attempt he has been moderately successful. The words employed are concise and yet perspicuity has not been sacrificed. The book is highly illustrated. Some of the plates are very good, others are only tolerably good, and a certain portion we are inclined to regard as rather poor. The first six chapters are devoted to the microscope, its history and importance its accessories, its use, and the modern method of examination, mounting, and preserving microscopic objects. We can but believe that some of these so-called "modern methods" are surrounded with an aroma of the past which should have excluded them from the third edition of an advanced work upon microscopy. For example, the process necessary to mounting of objects in balsam or dammar varnish, as given on page 79, is absolutely unnecessary, and we were glad to see that it was supplemented by a hint concerning another method which we believe to be far superior. Had the author given as concise a description of the method hinted at as has been given of the process which seem entirely unnecessary, he would have added material to the value of his book and avoided exciting in the mind of the student a contempt which is profanely a variance with the true spirit of microscopy. The seventh, eighth, ninth, tenth, and eleventh chapters are devoted to mineralogy, geology, chemistry, biology, vegetable histology and botany, and zoology. The

apters contain much that is interesting and readily comprehended by the student.

The Microscope in Animal Histology is the title of the twelfth chapter, in which are considered simple tissues, compound tissues, and organs of the body. The anatomical descriptions, in the main, are clear and meet the end designed in the construction of the book. The illustration of the uriniferous tubules varies somewhat from what we had supposed was the modern representation, and yet it may not be wise to say that it is incorrect. Just what the author means by the statement that "the peptic glands are blind tubes" is not quite clear, and we dare say will lead to some confusion in the mind of the reader.

The last chapter is devoted to the use of the microscope in practical medicine and pathology, and is in good keeping with those by which it has been preceded. The book is printed upon good paper, in a large clear type, and is well-bound, thus reflecting credit upon its publishers. In the absence of more extended treatises it is a convenient hand-book for students and amateurs in microscopy.

A PRACTICAL TREATISE ON THE DISEASES OF CHILDREN. By J. FORSYTH MEIGS, M.D., one of the Consulting Physicians of the Pennsylvania Hospital; Consulting Physician to the Children's Hospital, etc., etc., Philadelphia; and WILLIAM PEPPER, A.M., M.D., Prof. of Clinical Medicine in the University of Pennsylvania, etc., etc. Sixth Edition, Revised and Enlarged. Philadelphia: Lindsay & Blakiston. 1877. 8vo, pp. 1,012.

The excellence of this work is so well appreciated by the profession, and its reputation as a reliable authority is so well established, that it is unnecessary in noticing this edition to do more than state in general terms the additions and improvements which have been made. Besides undergoing a careful revision as a whole, some articles have been rewritten, as in the case of the one on cerebral congestion, and new articles introduced upon Night Terrors and Epidemic Cerebro-spinal Meningitis. We recommend the work as the best and most comprehensive one upon the subject in our language.

## Reports of Societies.

### NEW YORK MEDICAL JOURNAL ASSOCIATION.

Stated Meeting April 20, 1877.

DR. CHARLES M. ALLAN, PRESIDENT, IN THE CHAIR.

#### THE ABUSE AND USE OF BROMIDES.

R. E. C. SEGUIN, in an interesting and valuable paper, discussed the above subject under two heads: 1. Bromism, or intoxication by the bromides. 2. A statement of his own method of using the bromine salts in the treatment of epilepsy and other neuroses. Since the bromides had been brought into use in the treatment of neuroses, especially hysteria and epilepsy, Sir Charles Locock (1857), and systematized by Brown-Séquard, they had been employed in the treatment of an almost endless list of diseases and symptoms. The general use of the various bromides was largely empirical, the medicine being prescribed because of its quieting effect, and regardless of its physiological action.

Since 1867 experimental physiologists had been making researches regarding the effect of bromides

upon the healthy organism, and the most important conclusions reached were two in number. By some the bromides were believed to act by causing contraction of the arterioles and consequent diminution in the amount of blood in the nervous centres; while others claimed that they affected the nervous tissues directly. There was a general agreement, however, that the physiological result of the action of the bromides was lessened irritability of the nervous centres, especially in the motor tract.

Dr. Seguin believed that the bromides acted mainly by affecting the anatomical elements (ganglion cells chiefly) of the central nervous system. His belief was based upon physiological experiments in animals, clinical observations in man, and largely by the phenomena of bromism, which could hardly be explained by the vascular theory of the action of the bromides.

It was believed to be chiefly in consequence of the empirical notion that the bromides were indicated whenever there was excitement, aided probably by the extreme application of certain theoretical views regarding the physiological importance of changes in the amount of blood in the brain and spinal cord, that there had been, and still continued, an abuse or over-use of the various bromides. Cases were not infrequent in which a condition of impaired nutrition and nervous atony had been brought about and continued for months or years by the use of these medicines.

At this point Dr. Seguin divided his remarks into three sections: 1, concerning the general description of mild and of severe bromism; 2, respecting the complication which bromism might cause in diagnosis; and 3, with reference to the legal aspects of bromism.

#### VARYING DEGREES OF BROMISM.

In a number of cases Dr. Seguin had observed the following symptoms superadded to the legitimate symptoms of the disease: general debility, with weak pulse and coldness of the extremities; tendency to stupor; slight difficulty in speaking; the bromic breath, and acne. Those patients were weak, anæmic individuals, who had been taking the bromides for the relief of certain head symptoms, gratuitously supposed to be due to cerebral congestion. In some cases moderate doses of the drug had been taken for long periods of time, with frequent temporary relief to certain symptoms. All the time, however, the general condition of the patient had been kept below par, in spite of tonics and selected food. The same mild bromism had been noticed in some cases of hysteria and hystero-epilepsy, without any actual improvement. Injurious effects had been seen from the prolonged use of the bromides in the treatment of melancholia, a disease in which cerebral nutrition was quite surely lowered and perverted. Reference was made to a large class of patients who, without definite disease, suffered from nervousness, inability to sleep, queer sensations about the head, and who were inclined to constantly over-estimate their symptoms. To such patients the physician or druggist was very apt to say, "Take a dose of the bromides." It might be said that the administration of the bromides in such manner did not produce positive ill effects; but to that assertion Dr. Seguin replied by saying, *first*, that from what was known of the physiological effects of the bromides, such dosing must produce a general lowering of vitality which few patients could tolerate; and, *second*, that, on general principles, physicians were in duty bound to give no superfluous or non-indicated drug to their patients.

Allusion was then made to the more severe forms of bromism, in which the condition might obtain the dignity of a definite morbid state, have a clear symptomatology, a well-known course, and, as the doctor was disposed to believe, a central lesion. The symptoms of the more severe forms of bromism might be so aggravated as to simulate dementia, mania, or general paralysis of the insane, and even death might ensue from debility.

Dr. Seguin drew special attention to the resemblance between bromism and general paralysis of the insane. In both there was tremor of the facial and lingual muscles, producing a peculiar vibratory speech; in both there was an uncertainty in the performance of certain movements, as walking or using the hands for fine work; in both there was failure of intellectual force and of memory. Even somewhat exalted notions, though rarely, might be present in bromism. In general paralysis there were other important symptoms, such as contraction and irregularity of the pupil, sexual excitement, peculiar epileptiform seizures, remarkable remissions in the symptoms, and often good physical health, with tense arteries; all those symptoms being absent in bromic intoxication.

Severe bromism fortunately was rarely seen except in the early stage of the treatment of obstinate epilepsy. Bromism had been proposed as a cure for the opium habit, and the paper written by Dr. Schweig, of New York, upon that subject furnished a valuable study of the severe effects of the bromides.

BROMISM AS A COMPLICATION IN DIAGNOSIS.

Under that head reference was made to a case reported by Voisin. The patient had been under treatment for epilepsy, and, as his physician thought, becoming insane, was sent to Paris. He had been taking during some months bromide of potassium in doses of 90 to 120 grains. The patient was in a state of violent mania, and was removed to the asylum, where his case was looked upon by the officers of the institution as one of general paralysis of the insane. After the cessation of the bromides and the adoption of proper treatment, the man, at the end of thirteen days, was sent to his home in the country quite well.

Dr. Seguin then gave the history of a case which came under his own observation, and in which the addition of bromism to the other symptoms had led to the diagnosis of cerebral lesion of the gravest kind, when really only the basal dura mater was involved. The bromides were withheld and the iodide of potassium substituted, to give the patient the benefit of a doubt regarding the presence of a specific element. The symptoms of cerebral lesion passed away in a few days, and the local symptoms gradually disappeared, except the atrophy of the optic nerve.

THE MEDICO-LEGAL ASPECT OF BROMISM.

Bromism, although it has not been brought into the courts, might at some time appear under several circumstances.

*First*, with reference to the responsibility of the physician administering a medicine which produced such mental and physical debility as to expose the patient to various mishaps. For instance, a patient suffering from acute bromism had fallen asleep in a railway station and was robbed of four hundred dollars.

*Second*, with reference to the responsibility of the patient for committing criminal acts while suffering from bromism.

It was believed to be perfectly possible for such patients to take articles not paid for, through defective

memory; to be mistaken regarding the identity of persons, and thus be led to be abusive, etc.

*Third*, with reference to the legal capacity of brominized persons.

In some cases of bromism the stupor, loss of memory, and aphasiiform difficulty were so great that the patient was as truly *non compos mentis* as if he had a natural secondary dementia.

In certain cases it would be very difficult to reach a correct decision, because the judgment and general intellect were remarkably well preserved behind a display of superficial symptoms; and it also might be difficult to determine how much of the mental impairment depended upon the patient's antecedents, and how much upon the disease for which the medicine was taken.

*Fourth*, with reference to the production of death through bromism. There was a possibility that the procedure might be repeated with criminal intentions; perhaps for the purpose of getting rid of an incurable invalid.

METHOD OF USING THE BROMINE SALTS IN THE TREATMENT OF EPILEPSY AND OTHER NEUROSES.

1. The prolonged use of bromides was contraindicated by congenital feebleness.

2. The bromides were well borne by persons of fairly full habit and good nervous power.

3. The bromides were indicated in cases of abnormally great irritability of the nervous system in its motor (muscular and vaso-motor), and ideational tracts.

4. The contraindications above named were to be much less regarded in the management of that formidable neurosis, epilepsy.

5. Epilepsy was regarded as the only disease which justified the deliberate production of a degree of bromism for its cure.

Dr. Seguin's method of prescribing the bromides in the treatment of a case of "idiopathic" epilepsy was the following:

Two solutions were employed.

R. Potassii bromidi.....	gr. i.
Ammon. bromidi.....	ss.
Aque font.....	ʒi. viij.
M.	

S. To be given by the teaspoonful.

And

R. Sodii bromidi.....	gr. i.
Ammon. bromidi.....	ss.
Aque font.....	ʒi. viij.
M.	

S. To be given by the teaspoonful.

The quantity administered was, as a rule, so divided as to give by far the largest dose in the evening. The bromide was cautiously increased, still keeping the nocturnal dose the largest, until slight bromism was produced. It was usually necessary to maintain slight bromism for months, but just as little was to be given as would prevent the attacks. The precise quantity required must be studied in each case. Children tolerated the bromides, as well as the iodides, in relatively large doses. It was regarded as important to thoroughly dilute the bromides in order to facilitate their absorption—the dose to be taken in a wineglassful or half a tumblerful of water. Under no circumstances should the bromides be discontinued; they might be *diminished*, but not *stopped* until the word *cure* could be pronounced. They should be continued at least three years after the last attack. The adjunct treatment consisted in the use of measures to prevent the acne to a certain extent, such as the occasional use of

arsenic, sulphur ointments, mercurial plaster, and alkaline lotions; to correct the general debility or slight paresis, by the use of strychnia, nux vomica, oxide of zinc, and quinia; to relieve the dizziness by the inhalation of nitrite of amyl, by stimulants, and by quinia; regulating the patient's diet and hygiene, and the use of cream, cod-liver oil, iron, quinia, phosphorus, strychnia, with nitro-muriatic acid, wine, beer, or whiskey. In certain cases such medicines as acted more directly upon the morbid state of the nervous centres were associated with the bromides, and the favorite among those was belladonna. In the treatment of cases of epilepsy in which a definite causative lesion could be made out, the bromides were used simply to combat the habit.

In the treatment of other neuroses, Dr. Seguin had used the bromides sparingly, and never continuously. Bromism should not be produced in the treatment of *hysteria*, *Delirium tremens* might probably be shortened by the free use of the bromides.

Many cases of *insomnia*, treated upon the purely hypothetical indication of causing anæmia of the brain, might be much more quickly relieved by chloral, or by a glass of ale, or by correcting indigestion, than by the use of the bromides. Sleep was believed to be due partly to the general waste of tissues and the accumulation in the blood of the products of retrograde metamorphosis, and partly to the exhaustion of the cerebral tissue itself. The anæmia observed in the brain during sleep was regarded as a consequent phenomenon in obedience to the general law that a tissue in repose contained less blood than one in action.

In the treatment of *insanity*, the use of the bromides was recommended only to meet such indications as a tendency to epileptiform attacks, or abnormal sexual excitement, or great nervousness not caused by delusions. Favorable reference was made to the use of bromide of potassium before administering ether or opium with the view of preventing nausea and vomiting. Special attention was called to the use of bromide of ammonium in the treatment of *hay-asthma*—used as a gargle and to wash out the nasal passages several times a day with a weak solution of the same salt. The gargle was of the strength of  $\frac{1}{2}$  i. or  $\frac{3}{4}$  ij. to the  $\frac{3}{4}$  i. of water; the solution for the nares from 0 to 30 grains to the  $\frac{3}{4}$  i. of water.

## MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Stated Meeting, April 23, 1877.*

DR. JOHN C. PETERS, PRESIDENT, IN THE CHAIR.

### THE REVISION OF THE UNITED STATES PHARMACOPEIA.

THE discussion, relating to the modifications required in order that the Pharmacopœia of the United States might meet the wants of the medical and pharmaceutical professions, was opened by

DR. EDWARD CURTIS. He believed that the revision of the Pharmacopœia naturally belonged to the medical profession; that it should be placed under the control of that body which most perfectly represented the medical profession in this country, namely, the American Medical Association.

As at present constituted, the Convention for revising the Pharmacopœia met but once in ten years. The American Medical Association met annually, and certainly it was desirable that the organization having control of the book should meet sufficiently often to keep it in full pace with the advance made in our pharmaceutical and therapeutical knowledge. To do

that, an interval of ten years between the sittings of the Convention was altogether too long.

Another disadvantage associated with the present organization was, that the work was left for a committee to perform, the Convention dissolving for ten years. Suppose that such committee did not perform the labors assigned to it or carry out the instructions of the Convention, there was no redress for the profession until the close of the decade and the assembling of another Convention, unless some measure was instituted which should produce another book.

The matter being placed under the control of the American Medical Association, any neglect to obey instructions could be remedied yearly. Practically, the organization which had the Pharmacopœia in charge did not possess a national character, and the chances were that the book would come from a body which represented only a small portion of the country. The American Medical Association, which met yearly, was regarded as a much more perfect representation of the medical profession of the entire United States than the Pharmacopœial Convention, which assembled only once in ten years.

Dr. Curtis presented resolutions, which were referred to the Comitia Minora.

PROF. P. W. BEDFORD (pharmacist) remarked: It would seem from the argument made by Dr. Squibb in his circular, and set forth by Dr. Curtis, that the Convention which met every ten years to revise the Pharmacopœia had a certain definite sphere in which to act, and that that sphere of action continued from decade to decade. Such was not the fact. Each decennial convention prescribed its own rules for the performance of the labor assigned. Prof. Bedford was of the opinion that whatever of good there might be in the plan given by Dr. Squibb could undoubtedly be secured equally as well from the organization already in existence. For the real work of revising the Pharmacopœia finally reached a committee, and it would be the same should the Pharmacopœia be transferred to the American Medical Association. The final committee, in either instance, whether appointed by the present organization or in accordance with the new plan, would doubtless be composed of men who would be selected because of their adaptation and qualification for the work. But was the American Medical Association better qualified to secure the formation of a proper committee than a special convention called for that purpose? Prof. Bedford was not able to see wherein the committee, composed of men appointed by the new plan, could do the work better than the final committee appointed from the organization already in existence. He was unable to understand how the new departure was to secure a better Pharmacopœia. He did not claim that laws should be held to as unchangeable, but he did believe that the organization already in existence would proceed to form a Pharmacopœia, and the result would be that we should have two Pharmacopœias.

There was no reason why the present organization was not as much a national organization as the one contemplated by Dr. Squibb's plan. Various societies had the right to send delegates, and the representation could be from all parts of the country.

It should not be understood that the committee now in existence under the old organization—consisting of fifteen members—was the final committee to make the revision of the Pharmacopœia; it was simply a committee appointed to perform certain work, a labor of love, which would facilitate the labors of the final committee. It was to facilitate the work without

assuming the responsibility of revising and issuing the Pharmacopœia.

DR. W. H. THOMSON was of the opinion that both Pharmacopœia and Dispensary were sadly in need of revision to an extent almost equivalent to a recast. The mere perusal of the Dispensary was sufficient to convince one of the advancement which had been made in medicine in every conceivable direction. For example, one of the simplest of all the vegetable medicines was there mentioned as an alterative, a tonic, a febrifuge, a diuretic, a diaphoretic, and an expectorant. It was very much like recommending a man for a position by saying that he was a good banker, a good watchmaker, would answer as a dentist, and could serve as a sea-captain. The description of the action of medicines given showed that the greater part of the work in the Dispensary, rather the ideas and ignorance, were more than one generation entombed and kept in perfect preservation like ferns in beds of coal.

If the Pharmacopœia was to be a book for physicians alone, to assist them in the art of prescribing medicines, the American Medical Association, as representative of the medical profession, should assume the control of the work. If, on the other hand, it was to be a book to be used by druggists, and others who might have to do with the purchase and preparation of drugs and medicines, it did not belong so much to the medical profession as to the pharmacists. The more distinct those two things could be kept the better would be the results obtained.

If the control of the Pharmacopœia was retained by the pharmacists, the assistance of the physician was necessary, for the reason that, within the last ten years, a commercial element had been developed among druggists in the way of preparing and dispensing elixirs, special preparations of cod-liver oil, extracts, etc. Such an element came very near to the dispensing and sale of patent medicine. That condition of affairs should be regulated, not only by the Pharmaceutical Association, but, if necessary, by an official manifesto upon the part of the medical profession, and the question decided as to how far such preparation and sale should be carried. Certainly, any well-known and widely-used article, now sold as the exclusive preparation of any one druggist, should have its formula placed in the Pharmacopœia, so that it might be used by all druggists. The medical profession should hold the Pharmaceutical Association to the observance of such rules as would regulate the present condition of affairs in that particular.

DR. H. G. PIFFARD remarked that the Pharmacopœia of the present time was not a book upon which the druggist could wholly rely, but that the Dispensary was a necessity. In the Pharmacopœia there were scarcely any tests; no description of vegetable medicines, such as would enable a purchaser to determine whether he was obtaining the proper article; no indications as to whether proper manipulations had been performed in the compounding of medicines; no directions with reference to protecting certain articles against the influence of light; in short, the book contained but very little of what the druggist really needed.

We should hesitate before trusting the old organization with its revision. For, at the last Pharmacopœial Convention, certain instructions were given to the committee relating to the abolishing of measures of capacity, and adopting parts by weight, but those instructions had not been carried out. What was the guaranty that the instructions of the Convention would be better obeyed in the future? It seemed to him that the medical profession should unite in urging the American Medical Association to establish a

Pharmacopœial Council, in accordance with the plan proposed by Dr. Squibb. A council of that kind would be severed from all personal interest, and would best serve the interests of the medical and pharmaceutical professions.

The plan presented by Dr. Squibb was urged in preference to the older organization, and until some better one should be brought forward.

MR. PAUL BALLUFF, President of the College of Pharmacy, favored retaining the revision of the Pharmacopœia in the hands of the old organization. He believed all the objections to the book as it now stands, to the organization as it now exists, could be easily overcome without the formation of a new council, and thus any clashing of interests could be avoided. The deficiencies of the last edition could be supplied, the difficulty of obtaining the services of competent men without pay could be overcome, and the objection that the last edition was not followed at once by its commentary, the U. S. Dispensary, could be easily answered. He therefore urged that the work be conducted upon true democratic principles, and the old plan be tried once more.

DR. A. B. CROSBY believed that the plan for revision submitted by Dr. Squibb would obviate very decidedly some of the evils which had been complained of under the old system, and certainly would remove from the Pharmacopœia very grave suspicions, whether justly or unjustly, which had been cast upon it.

PROF. BEDFORD believed our Pharmacopœia to be as full as any other; did not think that there was any more league between it and the U. S. Dispensary than between any other two works; was not able to see where the experience especially adapted for such work had been obtained by medical men of the army and navy; and believed that the old organization could do anything and everything which that proposed by Dr. Squibb could perform.

DR. H. J. MENNINGER (pharmacist) maintained that the societies which sent delegates to make up the commission as it stands for revising the Pharmacopœia—namely, medical colleges, State medical societies, etc.—did not represent the medical profession of the country. The medical schools might be fountains of knowledge, but were not representative bodies of the medical community. On the contrary, the American Medical Association was a society which represented the medical profession of the United States.

The physician created the demand for medicines therefore should take the initiatory step in saying what preparations should be prescribed. For the mode of making those preparations the pharmacist was a necessity. Dr. Menninger regarded Dr. Squibb's plan as thoroughly representative, and one which would subservise the best interests of both professions.

DR. F. A. CASTLE spoke with reference to the deficiencies in the Pharmacopœia, and the lack of guaranty that the future edition under the old organization would be any better than the one already in existence. The medical schools had long since ceased to be the representatives of the medical profession hence an organization composed of delegates from such sources was much less democratic than one formed after the plan presented by Dr. Squibb.

DR. F. HOFFMANN (pharmacist) favored the plan which had been brought forward by Dr. Squibb for revising the Pharmacopœia.

DR. GOUVERNEUR M. SMITH was impressed with the democratic plan suggested by Dr. Squibb, and also believed that eminent ability was to be found among the medical men of the army and navy.

The PRESIDENT gave a brief history of the origin of the Pharmacopœia in this country.

There were *seventy* delegates in attendance upon the first National Pharmacopœial Convention, held in Washington, in 1820. At the present time only three States were represented in the Convention.

DR. PETERS did not regard the book of 1870 as good as that of 1820. In 1830 Philadelphia obtained absolute control of the book, and had retained it until she was laboring under the impression that she owned the Pharmacopœia of the United States.

When the English Pharmacopœia was revised, copies were sent to eminent medical men for suggestions, additions, and alterations, and when every alteration had been incorporated the book was printed. We had never had anything of that kind emanating from Philadelphia in connection with our Pharmacopœia.

The Doctor was of the opinion that the U. S. Pharmacopœia should approach more nearly to a national work than any other medical or pharmaceutical publication.

It was resolved to print the discussion, and continue it at an adjourned meeting. The Society then adjourned.

## Correspondence.

### A PLAN FOR CORRECTING THE ABUSE OF MEDICAL CHARITIES IN THE CITY OF NEW YORK.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Notwithstanding the great amount of good done, and the many really worthy and needy persons who receive help from our charitable institutions, it is well known that a large per cent. of patients who apply at the Dispensaries for medical attendance are abundantly able to pay a reasonable compensation for what they receive. This is an evil which will continue under the present lax system of *non-inspection*. It is generally known that none but reliable physicians are connected with these dispensaries, and that whoever applies will receive as good treatment as can be obtained in the city. For this reason this class of patients who are able to pay, but are unwilling to do so, or rather are willing to be classed as paupers, rarely come to the Dispensaries for their medical advice, knowing that their pecuniary status will not be questioned. This indiscriminate bestowal of charity, which thus encourages pauperism, is the fault of the institutions, not of the physicians, and the remedy, which is plain and simple, lies in the power of the institutions to effect.

I have considered the subject in all its bearings, and have broached this plan, which forms the motive of this paper, at different times during the past three years to prominent physicians and several gentlemen connected with various charities in this city. From such discussions, and from a large experience in Dispensary practice, I am convinced of the feasibility of the following plan:

A committee or General Board should be appointed on the Board of Trustees or managers of every charitable Dispensary and Hospital, including the Board of Charities and Correction, who shall apportion the city into *districts*, and appoint a *visitor* for each district; said visitor to be subject to such rules, regulations, and *salary* as the Board may consider proper. It should be agreed upon by the different institutions that no person should be allowed to apply

at a Dispensary or charitable institution without first having made application to the district visitor, who shall ascertain the pecuniary condition of the applicant, and such other information as may be required. Upon proof of the need of the applicant the visitor shall furnish an admission ticket for some *one* institution to be designated by the applicant, wholly independent of the prejudices of the visitor. The visitor should, however, be able to give such general information, if required, concerning the different institutions, as would be honorable and judicious. For entrance to the hospitals the applicant would, in addition, be approved by the Superintendent of the out-door poor. Each visitor should reside in his or her district, accessible to applicants, and should keep a record open for the inspection of the General Board. The salary of each visitor should be paid by a *pro rata* contribution from all the charitable institutions represented in the General Board. (It should be in proportion to the number of patients treated according to reports of the previous year.)

Patients who apply at a Dispensary in this way will be worthy of the charity extended, and pauperism will not be encouraged. It will be impossible by this means, under proper management, for *one* patient to visit three different dispensaries in one week, which is a quite common occurrence, and is certainly a most demoralizing as well as expensive custom.

This plan of district visitors has been tried and is still in force by one society, viz., the Society for Improving the Condition of the Poor; but as this is a work of charity, the visitors are members and give their services gratuitously. For the interest of the city and the mutual benefit of those institutions immediately concerned, it will readily be seen that visitors for this General Board should have a salary, as before stated.

The expenses of medical charities by this plan would ultimately be greatly reduced; self-imposed pauperism of this kind would be at a discount, if not utterly impossible, and, above all, the dignity of these same medical charities would be preserved.

H. T. HANKS.

149 LEXINGTON AV., 26th April, 1877.

### COLLEGE ENDOWMENT.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—"Alumnus," in Number 338 of THE MEDICAL RECORD, indulges in criticism and inquiries concerning the circular issued by the Alumni Association of the College of Physicians and Surgeons, relating to the collection of funds for educational purposes under the auspices of the College, and closes by saying: "Have the kindness in behalf of the Alumni to answer through your journal." If you will permit me to reply, I would say that the working men of the Alumni Association have presented to the Alumni of the College an appeal for funds in behalf of one branch of superior medical education, viz., Pathological Anatomy, for the benefit of Alma Mater and her present and future offspring. All that has even been said in Executive Council on this subject has been fully laid before all the Alumni who chose to attend the annual meetings of their own Association.

There is a pretended sincerity of innocent inquiry and a captious criticism in the letter of "Alumnus," to which all loyal graduates of the College of Physicians and Surgeons will feel disposed to take exception. Honest indignation will ask in return, where is the motive for, and what possible *concealment* is sought to be effected by a circular framed by the Executive Committee of the Association, under direct instructions

from the Board of Counsellors of the Alumni Association, and submitted by the Council for the information of the Association at its last annual meeting, at which meeting the circular was duly ratified and ordered to be printed and distributed. It is not to be supposed that any appreciative and filial graduate requires information on the subjects embodied interrogatively in the letter of "Alumnus," and information of the kind therein sought concerns none others.

Respectfully,

Secretary of the Alumni Association.

## A PROSTATIC GUIDE.

THE CABLE STYLET.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR.—Dr. Otis's description of his ingenious flexible stylet, to facilitate the introduction of a soft rubber catheter through a distorted prostatic urethra, which appeared in the RECORD of April 21st (p. 255), induces me to bring to the notices of the profession a similar instrument which I have been using for the same purpose during the past two years.

Squire's clever vertebrated catheter is not devoid of danger—in the hands of a patient at least. Some years ago a well-known instrument-maker of Philadelphia informed me that he had a letter from an old man in the country, asking for a Squire's catheter. The applicant said he liked the instrument, and had long used it upon himself, but the chain had broken in two previous instruments, leaving all the links behind in the bladder—therefore he wanted another!

In most cases of prostatic obstruction the soft rubber catheter finds its own way, and is an instrument absolutely safe in any hands. A little extra rigidity, which does not at the same time interfere with its perfect flexibility, is all the instrument requires in occasional difficult cases—of course where the obstacle is prostatic deviation, not urethral stricture.

An instrument which I have found to do all that was required as a flexible stylet is a portion of the cable of S. S. White's dental engine. This cable is a twisted rope made of one central and eight encircling very fine wires. It is a little smaller than Dr. Otis's guide, as made by Tiemann, and considerably more rigid than the flexible part of the latter. It is absolutely flexible in all directions, amply so for all cases I have encountered, not apt to get out of order, perfectly safe, and costs (being half a cable) exactly 75c. retail. A cable of five wires much smaller, more flexible, but less firm, has been made for me by S. S. White. Tiemann will have these guides on hand in the future, some of them flexible throughout, others rigid half way, and to sell either variety for 75c. or less. I propose to have a fine guide covered with rubber to use as a flexible probe.

Dr. Otis's new instrument is in principle much the same as the old one I have been using, and perhaps has some advantages, but the latter is cheaper, smaller, more durable (I should judge), and has stood the test of a couple of years' trial. It would be well to try both in difficult cases, before being absolute about their respective merits.

E. L. KEYES.

210 MADISON AV., APRIL 20, 1877.

MEDICAL SOCIETY OF NEW JERSEY.—The next annual meeting of the Medical Society of New Jersey will be held in the Assembly Rooms, Taylor Hall, at Trenton, on Tuesday, May 22, 1877, at half-past seven P.M., and will continue in session the following day.

WM. PRERSON, JR., Secretary.

DR. HARVEY HOLMES GREGORY, who suddenly expired at his residence in Harlem, at an early hour on the 1st instant, was born Oct. 2, 1829, at Modena, Ulster County, N. Y. He was the eldest son of Milton S. Gregory and Charlotte P. Holmes, his wife. His academic education was received at the Amenia Seminary, Dutchess County; his medical, at Castleton, Vt., and the College of Physicians and Surgeons, New York, from which latter institution he was graduated in 1853. After a brief residence in Williamsburgh, now Brooklyn, E. D., he commenced the practice of his profession in Harlem when it was a mere suburban village, and there he remained until the date of his death. The doctor was thoroughly identified with the religious, educational, and political interests of his chosen residence, for the enthusiasm of his nature would not permit him to play an unimportant part in any position in life. He also thoroughly loved his profession, was active and untiring in his ministrations, warm-hearted and devoted in his friendships, candid and outspoken in his opinions. Of a rare and genial humor, he became, in truth, "the beloved physician," more careful of others' interests than his own. During an active practice he garnered up rich stores of knowledge, which he freely dispensed in conversation and at medical reunions. Original and independent, always utterly devoid of jealousies, he almost stood alone among his peers, all unconscious of his personal magnetism. He died with his harness on, the type of many a general practitioner, who lives immortal in the tender memories of his patients.

NEW YORK COUNTY MEDICAL SOCIETY.—At a stated meeting held April 23, 1877, it was voted to grant certificates of membership to the following gentlemen: Drs. F. C. Robinson, H. A. C. Anderson, W. S. Hurd, Ernst F. T. Horst, E. C. Mann, G. A. Evans, C. M. Desveraine, W. DeF. Day, N. S. Roberts, W. S. Studley, and E. Passmore.

The paper for the next stated meeting will be read by Dr. H. B. Sands, upon "The Treatment of Intussusception by Abdominal Section."

## Original Lectures.

## PULMONARY EMPHYSEMA — ABSENCE OF ATTACKS OF SPASMODIC ASTHMA.

## A CLINICAL LECTURE

DELIVERED AT THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK CITY.

By FRANCIS DELAFIELD, M.D.,

ADJUNCT PROFESSOR OF PATHOLOGY AND PRACTICAL MEDICINE.

[Reported for THE MEDICAL RECORD.]

GENTLEMEN:—We have here a history, dating back perhaps a little more than three years, and beginning with cough and shortness of breath. The shortness of breath is pretty distinctly due to exertion, for the man at no time has suffered from attacks of dyspnoea at night, nor has he suffered from difficulty in breathing when at rest. The moment, however, he begins to walk shortness of breath commences, and before he has walked one block he is compelled to stop and rest. Three years ago he spat up probably about four tablespoonfuls of blood, fresh and frothy, and between that time and the present the sputa have occasionally been streaked with blood. His cough has not been very troublesome, but has occurred something as follows: some time during the day he feels the necessity for coughing, and commences; the cough soon becomes partly paroxysmal and continues until a small quantity of mucus is raised, whereupon it ceases and does not begin again until the same desire recurs. There has been no swelling of the feet, no nausea, and no diarrhoea. He looks in tolerably fair condition, and does not feel particularly sick, except for the shortness of breath.

This is the history of the case, and from such a history we would say that the shortness of breath probably depends upon some cardiac disease rather than disease of the lungs. There is nothing certain in such an assumption, but the probabilities are in its favor. If the difficulty is dependent upon lung disease instead of cardiac, there are two conditions which might give rise to such symptoms as we have here, namely, emphysema and phthisis. Either alone could give rise to such a history, and still more certainly the combination of the two, for the two may occur together. The question, however, can be settled only by physical examination.

As the chest is laid bare a distinct epigastric pulsation can be seen. The apex of the heart cannot be felt, and there is no abnormal cardiac murmur. There is no evidence of hypertrophy of the left ventricle. The dyspnoea, therefore, is not dependent upon cardiac disease. We will next examine with reference to pulmonary disease.

As I percuss this man's chest I get a kind of resonance which is often present with emphysema of the lungs. It resembles pulmonary resonance, except that the pitch is higher; it is not tympanitic at all; it is not particularly sonorous; it is really more like dulness, and yet it is not exactly dulness; a wooden tone, or a rather high-pitched pulmonary resonance is perhaps as good a description as can be given.

On auscultation the expiration is moderately prolonged over both lungs anteriorly. There are no râles over the upper part of the chest, but over both epogastric regions a good many subcrepitant râles can be heard.

Posteriorly there is increased resonance upon both

sides, and a few subcrepitant râles can be heard over the lower portion of both lungs. There is also prolonged expiration upon both sides of the chest.

The physical examination, then, gives no evidence of cardiac disease, and with reference to the lungs shows us in front a resonance rather higher pitched than normal; behind, exaggerated resonance, subcrepitant râles over the lower portion of the chest, and prolonged expiration over the entire chest. There is no marked dulness at any point.

The physical examination points to the existence of emphysema of the lungs. But you will observe that with the emphysema the spasmodic element is entirely absent. The man has emphysema and the dyspnoea dependent upon it, but he has none of the asthmatic attacks which so frequently accompany it. He has emphysema without asthma, if you keep the term asthma to designate the spasmodic form of affection.

The condition of the bronchi corresponds to this conclusion. There is apparently only a moderate amount of bronchitis in this case, while in most cases of emphysema there is considerable chronic bronchitis, and the bronchitis apparently plays a considerable part in the production of the dyspnoea from which that class of patients suffers. I should imagine that the absence of bronchitis in this case had much to do with the absence of spasmodic attacks of dyspnoea.

Although we do not get the sibilant, sonorous, and coarse râles which go with bronchitis and emphysema, on the other hand there is a physical sign present which points to a different complication of the emphysema. There are fine subcrepitant râles over the lower portion of the lungs, and such râles, without the coexistence of the coarse râles alluded to, indicate that the patient has, in addition to his emphysema, a certain amount of chronic interstitial pneumonia. That is, besides the dilatation of the air-cells which he has, there are nodules and points of fibrous tissue scattered through the lungs, or, as in the present case, confined to the lower part of the lungs.

These fibrous nodules and points seem to have no connection at all with phthisis; they seem to be a true interstitial pneumonia, simply a new growth of connective tissue between the air-vesicles occurring as a complication of emphysema. How much worse off the patients are who have this interstitial pneumonia, I do not know. It does not seem to add to their symptoms, for they have about the same amount of dyspnoea, whether they have interstitial pneumonia or not. At all events, in the severer cases of emphysema, especially with such physical signs as we have here, there is frequently evidence of such a new growth of connective tissue between the air-cells of the lungs.

Now, with reference to prognosis and treatment. As far as duration of life is concerned, prognosis is good; but with reference to the dyspnoea, it is unfavorable. His dyspnoea is likely to continue. The fact that it has been getting worse during the last four years is rather against him. Still he may improve to such an extent as to again be able to do a moderate amount of work; probably, however, he will never be able to perform very hard labor.

As regards treatment, we have in this case comparatively little to get hold of. In most cases of emphysema we really treat the bronchitis, for it is apt to be the complication which gives rise to many of the symptoms.

In this man there is but a very small amount of bronchitis. I should not, therefore, be disposed to give him any of the remedies ordinarily employed, but simply pay attention to his general health. Per-

haps he would receive some benefit from the use of cod-liver oil, iron, and quinine, continued steadily for some time. Iron and arsenic, perhaps, may be given in small doses with benefit.

The case is one of interest, because it differs from most of the cases of emphysema in that there is absence of bronchitis. There is a large amount of emphysema and great dyspnoea resulting from it, and yet there is present only a very slight amount of bronchial trouble.

#### EMPHYSEMA AND CHRONIC BRONCHITIS.

This man tells us that he has suffered from chest trouble during the last three or four years, and that it has gradually increased in severity until last December, when he was obliged to stop work. His chief complaint is, that he is short of breath all the time, and has cough, with considerable expectoration.

Occasionally the shortness of breath wakes him up, but as a rule he sleeps naturally in bed. He has not been obliged to get up but once on account of his dyspnoea. Three years ago he raised a small quantity of blood. His appetite is fair, and his general condition is very good.

*Physical Examination.*—There is no evidence of cardiac disease. Here again we have an example of that peculiar kind of resonance, already described, which is more characteristic of emphysema than tympanitic resonance. Upon auscultation, expiration is decidedly prolonged over the anterior portion of the chest, and the same is heard behind. The prolongation approaches a sibilant. There are no râles heard, except a few localized in the left suprascapular space. His voice gets hoarse at times, and his wife says that he breathes hoarse during sleep.

This case, then, seems to be an ordinary one of emphysema and chronic bronchitis, in which there is dyspnoea upon exertion, and also when the man is quiet. He has had as yet only one attack of spasmodic dyspnoea, but apparently it is gradually approaching that character. His cough and expectoration, and also his breathing, indicate trouble with the bronchi. At this particular time there are no râles, but probably at other times coarse râles can be heard. He has, however, a prolonged and sibilant breathing, which accompanies chronic bronchitis, and is quite as indicative of that disease as is the presence of râles.

The fine râles heard at the apex of the lung upon the left side, posteriorly, rather point to lung consolidation.

In this man we have a case to treat somewhat different from the preceding. It is a case in which it would be proper to administer the remedies commonly employed in the treatment of emphysema with bronchitis, such as the iodide of potassium, wine of ipecac, Hoffman's anodyne, etc.; but he has taken all these without benefit. He has also taken iron and quinine, and he is still getting worse, instead of better. He has also taken cod-liver oil, and yet his condition has not been improved.

There is a remedy which sometimes answers in these cases when iodide of potassium and all others have failed, and that is sulphuric acid. To be of service, it should be given in rather larger doses than those ordinarily administered. It will be ordered in this case in twenty-drop doses, aromatic sulphuric acid, four times a day. While the patient is taking this remedy all others will be discontinued except the oil, which may be continued with advantage.

In order to determine whether the acid is to give any benefit, it should be continued for at least three weeks. If, at the end of that time, the breathing is the

same, you may be quite sure that the acid does no good, and it would then be proper to make a trial of some other remedy.

#### SUPPURATIVE INFLAMMATION OF THE STERNO-CLAVICULAR ARTICULATION IN THE COURSE OF ACUTE ARTICULAR RHEUMATISM.

This case possesses considerable interest from the fact that, although only this single small joint is affected, yet it may terminate fatally. The girl says that she had rheumatism last September, from which she had not fully recovered when this inflammation of the sterno-clavicular articulation upon the right side began to be developed. The joint is now exceedingly tender and is quite painful. A little farther down there is a localized soreness and pain connected with the periosteum of the sternum.

This kind of inflammation of the sterno-clavicular articulation, in the cases in which I have seen it, has been rather troublesome, altogether out of proportion to the size of the joint involved.

Whether accidental or not I am unable to say, but the cases have all gone on to suppuration. They began, as in this case, in connection with rheumatic inflammation, then changed into a suppurative inflammation, with distinct collection of pus about the joint.

There is apparently no pus here at present, and we have to deal with a simple rheumatic inflammation. The pain which has brought the girl here, and which is referred to the left side, is really the least important part of her case. That which requires special attention is the rheumatic condition showing itself in this joint. To subdue that I should place her at once upon considerable doses of colchicum and iodide of potassium. I should not stop to wait for the effect of salicin or salicylic acid in such a case as this.

Colchicum has its disadvantages, but it operates more rapidly in subduing such an inflammation as we have here than any drug we possess. I should first administer ten grains of the iodide of potassium, combined with ten drops of the wine of colchicum, three times a day. If the colchicum is borne well I should repeat the doses more frequently, gradually increasing the frequency to four, five, or six times a day, and should keep it up as long as the remedy does not disturb the stomach or bowels. The treatment should be prompt and decided. In two cases in which I have seen the suppurative inflammation of this joint in connection with rheumatism it has given rise to general pyæmia and death. One patient was a little girl who, from playing in the snow, developed acute articular rheumatism, which was attended by abscess of this joint and subsequent general pyæmia. As stated, the case terminated fatally. The second case had a similar history. It is well, therefore, for you to remember that, although this articulation is small, it may become involved by suppurative inflammation in the course of acute articular rheumatism, and give rise to very serious disturbance.

A SUMMER SCHOOL OF BIOLOGY, under the direction of the Peabody Academy of Science, will begin a Salem, on the 6th of July, and continue six weeks. Wednesdays will be devoted to dredging trips, the remainder of the week being occupied in the laboratory lectures, and excursions; the special object being to give instruction to teachers in methods of teaching natural history. Special attention will be given to entomology and to the anatomy of vertebrates. The instruction will be under the immediate direction of Dr. A. S. Packard, Jr., assisted by Messrs. Emerton Kingsley, Robinson, and Bolles.

## THE ENCEPHALIC CIRCULATION :

## ITS MECHANISM AND RELATION TO VARIOUS CEREBRAL FUNCTIONS.

By REUBEN A. VANCE, M.D.,

GALLIPOLIS, OHIO,

(President of the Ohio Valley Medical Association.)

A paper, the substance of which was read before the First Section of the American Medical Association, June 2, 1874, and in its present form was brought before the Ohio Valley Medical Association, Nov. 8, 1876.

THERE are few questions in practical medicine which have given rise to more controversy, or been the subject of more conjecture, than that of the circulation within the cranial cavity. For a correct understanding of the intra-ocular changes which are observed to occur with the various forms of cerebral and spinal diseases, it is essential that the physiological processes whereby the brain is nourished in health, the variations which occur normally, and the phenomena presented by the circulatory system in disease, should be thoroughly comprehended. The intimate connection existing between the intra-cranial and intra-ocular circulations will render necessary a brief description of some anatomical points which will throw light upon certain physiological changes to which they are subject in common.

The main points at issue in regard to the mechanism of the encephalic circulation relate to the atmospheric pressure, the variability of the quantity of intra-cranial blood, and the power of the heart to exert a compressing influence upon the tissues of the brain by any influence that can be communicated through the carotid and vertebral arteries.

The bones of the cranial cavity form an unyielding case in which the nervous tissues of the encephalic centres, their membranous coverings and nutritive vessels, are packed with the utmost compactness and nicety. Intimately attached to their inner surface is the dura mater, which forms their internal periosteum, and is prolonged into the spinal canal, where it constitutes the external layer of the theca of the cord. The cranial nerves, as they emerge from the skull, are invested with a covering from the dura mater, the encephalic sinuses are situated in layers of its substance, while partition-like processes serve to separate and support different divisions of the brain.

The pia mater, the most internal of the membranes of the brain, and the one directly in contact with its surface, closely invests the cortical layers of the supreme centres, and is prolonged into the general ventricular cavity. It is the medium through which the nervous structures of the encephalon receive their nutritive supplies, and is situated between the brain and the arachnoid membrane. The arachnoid differs in no essential respect from the other serous membranes of the organism. Like the dura mater and pia mater, it is continuous with similar structures surrounding the spinal cord. It lines the internal surface of the dura mater in the cerebro-spinal cavity, and invests the pia mater, forming a closed sac, the highly polished surfaces of which are in immediate contact. It is never prolonged as a covering to the nerves which leave the brain or spinal cord, but at the point where they pierce the dura mater is reflected on the internal surface of that membrane. Its visceral layer does not penetrate the ventricles, neither

does it dip into the sulci between the convolutions; it simply invests the external surface of the pia mater loosely, and at certain situations its arrangement enables the serum, with which the brain is abundantly supplied in health, to accumulate in considerable quantity.

The cerebro-spinal serum is found wherever the pia mater is situated, whether in contact with the brain or spinal cord, on the surfaces of both organs, and in the ventricles of the former. It fills the various inequalities of the cranial and spinal walls, but accumulates in greatest quantity where the subarachnoid space is most abundant. At the base of the brain two large reservoirs can be observed, one behind and below the cerebellum, corresponding to the posterior surface of the medulla oblongata, enclosed behind by the layer of arachnoid which passes from the medulla to the cerebellum, and one in front, extending from the anterior surface of the pons Varolii to the commissure of the optic nerves, occupying the central depression between the middle lobes of opposite sides, and bathing with its fluid the basilar and cerebral arteries, the chiasma, the tuber cinereum and infundibulum. Near the level of the corpus callosum, above the tubercula quadrigemina and behind the pineal gland, can be found a third receptacle, in which this extravascular serum accumulates in considerable quantity. The subarachnoid space of the spinal cord contains this liquid in abundance, and the anatomical structure of the parts is such that it can readily pass from the cranial to the spinal cavity, and *vice versa*.

The arterial supply of the brain is, in many respects, peculiar. The main arteries which penetrate the skull are provided with an anastomosis (the circle of Willis), which is very complete; the large branches which originate from it traverse the sulci of the convolutions before dividing into the network of vessels which, in great part, constitute the pia mater, and but few trunks of considerable size enter the cerebral substance. This extensive division and subdivision of the arterial vessels in the membrane which invests and lines the intra-cranial nerve-centres, undoubtedly operates to protect those delicate parts from the commotion incident to arterial pulsation, while the free anastomosis thus established prevents disturbance of the cerebral circulation from slight and transient causes. The extravascular serum which surrounds the larger vessels at their entrance, and accompanies the branches in their course, by the facility with which it is increased or diminished, would seem adapted to compensate for an increased or diminished amount of blood in the main vessels, without disturbing the equilibrium of the brain.

The researches of Robin and His have demonstrated another anatomical peculiarity which illustrates still more the conservative provisions with which the brain is endowed, and supplies the missing link which was necessary for a complete conception of the physiological actions of the encephalic structures. This is the discovery of a system of lymphatic sheaths, enclosing spaces around the blood-vessels, revealing a structural adaptation which seems especially calculated to permit of varying amounts of fulness of the cerebral vessels within certain limits, without injury to or compression of the surrounding nerve-pulp. Professor His has succeeded in injecting this system of perivascular canals, and has found them most numerous in the gray matter of both brain and spinal cord. He has found the injections come to the surface of the encephalon and cord, and fill a vast system of lacunæ situated between the pia mater and the surface of the

nervous centres, whilst, if pushed still farther, he has found it fill the lymphatics of the pia mater itself. Thus there is, as it were, a second series of vessels enclosing and surrounding with a fluid medium all the ramifications of the cerebral and spinal vascular system, whilst these two sets of vessels, containing and contained, are lodged in definite cylindrical canals, permeating the nerve-substance in all directions. The lymphatic sheaths are in contact with, though easily separable from, the walls of the canals in which they are contained. The diameter of these canals, and therefore of the lymphatic sheaths, may be seen in transverse sections to be generally twice and sometimes three or four times as large as their contained blood-vessel. It will be easily understood that these two systems must have such a complementary relationship to one another that an extra state of fulness of one set of vessels must correspond with diminished fulness of the other set. That is to say, in order to make room for an increased amount of blood in the cerebral vascular system, a corresponding amount of fluid must be driven out of the enveloping lymphatic sheaths, whilst, when the vascular supply is again diminished, a proportionate amount of fluid re-enters the cerebral lymphatic canals.\*

It occasionally happens that the physician has an opportunity of observing the phenomena presented in cases where a portion of the bony investments of the brain have been removed, either as a consequence of disease, or of surgical operation. It will then be apparent that, during the circulatory and respiratory movements of the heart and lungs, the brain undergoes marked and decided alterations of volume. Should the membranes be ruptured also, other phenomena will be apparent. The connection between these movements, which require such exceptional circumstances to render them apparent, and the changes which ensue in the brain when invested by its natural covering, is of such an interesting nature and so closely connected with many of the pathological states of that organ, that it is deserving of consideration.

When from any cause a portion of the cranial parietes has been removed, exposing the membranes of the brain, it can be observed with each contraction of the heart, and each respiratory movement, that the tension and prominence of these membranes will vary. The cardiac systole will be attended by an increased size, a visible enlargement and swelling of the exposed parts, which will approximate, or even pass, the osseous boundaries of the cavity through which they can be seen, and the sense of touch will show that this action is accompanied by a pulsatory movement of the same nature as that attending the dilatation of arteries in other parts of the body. With the diastole the membranes diminish in size and recede within the cranial walls. These appearances vary with the intensity and rapidity of the heart's action.

The respiratory movements are accompanied by phenomena not less apparent. With inspiration the volume of the brain, as exhibited by the parts under examination, will diminish, the membranes recede and become depressed. With expiration they expand, grow prominent, and pass beyond the boundaries of the skull. The movements synchronous with the cardiac systole and diastole may be observed during both inspiration and expiration, but are much more marked during the latter. When from accident, in addition to the loss of bone, there is perforation of the membranes, each expiratory act will be accompanied by

protrusion of a portion of the cerebral substance, constituting *hernia cerebri*.

The phenomena attending sleep and wakefulness are not less marked. During the hours of active exercise and ordinary mental excitement, the situation of the membranes, as regards degree of approximation to the opening in the skull, will differ widely from their position during the repose of sleep. In the first condition, aside from the respiratory and cardiac movements, the membranes will be observed tense and distended; in the latter they will be lax and flaccid. In the one case they will be much nearer the opening in the parietes than in the other, their resistance to pressure and apparent vascularity will likewise present differences easily recognized. In brief, sleep will be attended by a diminished size and an anæmic state of the exposed membranes, while wakefulness will be accompanied by protrusion and hyperæmia of the same parts.

The various medical writers who have treated of the cerebral circulation can scarcely be said to have thrown much light upon the subject. The experiments of Monro, Kellie, and Burrows, the speculations of Abercrombie, and the teachings of Watson, Williams, Tod, and Bennett, while they clearly express the views warranted by the anatomical and physiological knowledge of the times in which they were formed, were radically defective in many important respects. The *à priori* conceptions they carried to their work are apparent in the results they attained, and it is only by the light of a more perfect anatomy and a more advanced physiology that we can, at the present day, arrive at results which, to say the least, contain fewer elements of error.

The different authors I have mentioned, with Reid, Copland, Kirkes, Carpenter, and Arnott, whilst disagreeing more or less regarding the variability of the circulation within the cranium, its amenability to atmospheric pressure, the power of the heart to exert a compressing influence, and the importance of the cerebro-spinal fluid, are in harmony so far as regards the general admission of a state of intra-cranial fulness—a condition in which its fluid and solid structures accurately fill the cranial cavity. The question of an intra-cranial *plenum* is undoubted, but the variations in the relative quantity of the different fluids, with the circulatory and respiratory movements of the brain, its anæmic condition during sleep, and its vascular state during wakefulness, have not been set forth with the clearness and precision their physiological importance warrants, and need a few words in explanation.

In the normal condition the brain floats upon, is surrounded with, and permeated by the extra-vascular serum which accumulates at the base of the skull, permeates the pia mater wherever situated, and invests the vascular trunks contained in the lymphatic sheaths which penetrate its substance. This liquid communicates freely with the ventricles of the brain, and flows readily from the cranial to the spinal cavity. When the bony investments of the encephalon are intact, the contraction of the heart is attended by the propulsion of an increased amount of blood into the cranial cavity—an amount greater than can be compensated for by the quantity which is returned by the veins during the same interval of time—and, as a consequence, an amount of serum corresponding to the increased quantity of blood is forced from the cranial to the spinal cavity. With the cardiac diastole the tension of the arterial trunks is lessened, capillary attraction carries the new blood into the veins, and atmospheric pressure operates to draw back into the cranial cavity the serum just expelled. With each movement of the heart this interchange takes place—every systolic contraction is at-

\* Eastman: *Reynold's System of Medicine*. Art., "Congestion of the Brain."

tended by a flow of serum from the brain to the spinal cord, and the succeeding diastolic relaxation is attended by its return to the cranial cavity.

The mechanical forces in operation during respiration produce certain definite changes in the volume and appearance of the encephalic structures. The inspiratory act is accompanied by descent of the diaphragm and elevation and lateral expansion of the ribs, enlarging the cavity of the chest in all directions. One immediate effect of this general enlargement is to draw, as it were, the blood from the large venous trunks in the vicinity into the right ventricle of the heart, and this action is an important element among the forces which operate to maintain the general or systemic circulation. During the inspiratory act the blood is withdrawn from the cerebral sinuses, and this suction force may be so great as to cause collapse of the superficial veins of the neck. The phenomena of expiration due to the stagnation of the venous blood are equally marked and decided. The ascent of the diaphragm and subsidence of the chest-walls are accompanied by a temporary suspension of the flow of blood to the heart from the cerebral sinuses, while the uninterrupted activity of that organ continues to send an increased amount of blood into the brain. The consequence is, that while the normal quantity of blood is propelled into the intra-cranial cavity, comparatively little, if any, is discharged from it, and an unusual amount is lodged in its vascular system. As a result, the extravascular serum passes to and from the spinal cavity with each respiratory movement, flowing into the cranial cavity during inspiration, to supply the place of the blood drawn from the sinuses by the dilatation of the chest-walls, and returning during expiration as a consequence of the retardation of the venous flow which ensues from their contraction.

The movements which can be observed in the membranes and substance of the brain when the skull is perforated do not occur in its normal state. The alternate dilatation and contraction of that organ during the movements of respiration and circulation, which can be seen when a part of the cranial parietes have been removed, are not possible when the encephalic coverings are intact. The varying states of vascular fullness corresponding with these physiological movements are then compensated for by the flux and reflux of the extravascular serum in the manner indicated.

The conditions of sleep and wakefulness are accompanied by alterations in the tension and vascularity of the exposed membranes. In sleep they grow flaccid, and their blood-vessels diminish in number and size, whilst, during wakefulness, they are prominent and vascular in proportion to the state of mental or bodily activity. When the coverings of the brain are intact, the anæmic condition of the cerebral organs during sleep is accompanied by the presence of an additional quantity of serum around the vessels, in the meshes of the pia mater, and the ventricles of the brain; whilst, during wakefulness, the vascular trunks enlarge, and the serum is forced from the cranial to the spinal cavity.

The pulmonary and abdominal organs are invested by a serous membrane of the same nature as the arachnoid, and analogous offices are performed by these structures in common. The most prominent of these is the facilitation of motion by their polished surfaces. This can be seen in great perfection in the movements of respiration, whereby, through atmospheric pressure, the lung substance remains in contact with the chest-walls during inspiration, and during expiration in the return of the abdominal viscera to their proper positions. The unyielding bony structures external to

the arachnoid, being motionless, do not act so as to cause the visceral layer to move in order to keep in contact with its parietal layer, as the surfaces of the pleura and peritoneum are forced to do, yet atmospheric pressure, which operates to keep the serous surfaces of those organs in apposition, and produces many of the visible phenomena of respiration, preserves the character of the arachnoid as a closed sac, keeps its surfaces in contact, and maintains the fluid contents of the skull at a uniform quantity. For the due performance of the physiological movements of the brain, the arachnoid sac, and extravascular serum are as important as the cavities of the pleura, the contractile muscles, and the inspired and expired air are to the movements of the chest during respiration.

Cases of disease exemplify what it is reasonable to infer from the anatomical structure and physiological peculiarities of the intra-cranial organs in relation to the ability of the heart, under certain circumstances, to exert a compressing influence upon the encephalic substance. It is necessary, however, that all the serum should first be expelled from the perivascular sheaths, and in great measure from the meshes of the pia mater, before the cardiac impulses can affect the nervous tissues, and, as a general rule, this is only possible in those cases where, from the continued distention due to prolonged functional activity, the muscular coats of the vessels have lost their contractility.

In conclusion, the peculiarities of the cerebral circulation, including the various disputed points, can be summarized as follows:

*First.* Atmospheric pressure operates in such manner as to keep the fluid contents of the skull at all times the same;

*Second.* The heart can, under certain circumstances, exert a compressing influence upon the encephalic structures; and

*Third.* The relative quantities of arterial and venous blood and extravascular serum vary with,

1. Cardiac contractions;
2. Respiratory movements;
3. Sleep and wakefulness; and,
4. Mental excitement and repose.

#### TRACHEOTOMY IN DIPHTHERIA— FOUR SUCCESSFUL CASES.

[DURING the past few months we have received the following cases, and thinking it desirable to place them upon record, we group them for convenience under one heading:]

BY A. ROSE, M.D.,

NEW YORK.

*Case I.*—In the evening, on November 2, 1875, I saw for the first time Mr. L.'s child, a boy aged three years. I ascertained that he had been in perfect health on the evening of the 1st November, having eaten the supper with a good appetite; that he, however, awoke with symptoms of dyspnoea on the following morning, and grew rapidly worse. I found great difficulty of breathing, with energetic contraction of the muscles of the anterior thoracic wall, each inspiration causing a deep groove, corresponding with the place of insertion of the diaphragmatic muscle at the lower end of the sternum; at the same time there was a stridulous noise, the lips were of a blue color, and on the faces there was diphtheritic exudation. Having obtained the consent of the parents, I performed tracheotomy immediately, with the kind assistance of Dr. B. Scharlau. The child was quite insensible to pain, and no anæsthetic was necessary.

While cutting down to the trachea, close under the isthmus of the thyroid gland, I found a well-developed network of veins, some of which I was forced to sever. Considerable bleeding took place, but by the application of 6-8 ligatures I succeeded in arresting all hemorrhage before I opened the trachea. After the incision was made and the canula inserted respiration became immediately easy and normal. The child soon took liquid food, and seemed to improve during the night. During the next forenoon, however, symptoms of paralysis returned. Quinine, camphor, and benzoic acid were administered internally, but death ensued eighteen hours after the operation.

*Case II.*—On November 13th I performed tracheotomy, with the kind assistance of Dr. H. von Seyfried, on a little girl, three years old, the daughter of Mr. R. I had seen her for the first time on the 7th of November, when I already had observed difficult respiration. Although no diphtheritic deposit could be found, I had reason to presume an attack of diphtheria, and prescribed accordingly. I did not see the child from the 8th to the 12th of November, but was informed that the dyspnea continued, with intervals, during the entire period, and finally it increased so much as to necessitate an operation. The same characteristic symptoms of difficult respiration were observed as in the first case. Chloroform was administered. On account of the presence of a middle lobe of the thyroid gland, and for other anatomical reasons, I was compelled to cut through the gland along the median line, which being done, I soon succeeded in laying open the trachea; there was also considerable hemorrhage, but it ceased as soon as the tube was inserted.

The respiration of the child was at first irregular, but it soon improved after large diphtheritic membranes were coughed up. Towards evening it whispered a few words, which were understood by the mother.

*November 14th.*—Temperature 103, pulse 160. Membranes continue to be coughed up. Dulness of small extent on percussion and diminished respiration posteriorly and below on the left side. Five grains of quinine every two hours.

*November 15th.*—Temperature and pulse about the same; membranes expelled. Two doses of quinine, of ten grains each.

*November 16th.*—Temperature 101, pulse 130. Dulness on percussion has disappeared, moist râles on the right side above. No more membranes, but only catarrhal secretion instead.

The child now improved rapidly. On the 17th she took her food together with the other children, and was able to speak plainly whenever the tube was closed. A moist sponge was attached to the external opening of the canula. In order to prevent the drying of the tracheal and bronchial secretion, and the consequent clogging of the tube, I employed Dr. A. Jacobi's method of lubricating the inner tube with glycerine whenever it was taken out for the purpose of cleaning. The proliferous granulations of the wound were cauterized with a strong solution of nitrate of silver.

There are seven children in the family, ranging from one to twelve years. They live on the first floor of a rear tenement house; the room in which I operated serves as a living, sleeping, cooking, and eating room; the door opens immediately into the yard. The small supply of light embarrassed me greatly during the operation; yet, in spite of all these drawbacks, the little patient has steadily improved. At the time of reporting the case she still wears the outer tube, which, during the day, is closed by a piece of cork.

236 SEVENTH STREET.

By GEO. A. HAQUNGA, M.D.,

NEW YORK.

*Case III.*—Sarah Ellen C., aged five years and three months; subject to tonsillitis (otherwise healthy); had a portion of both tonsils excised about fourteen months ago for "hypertrophy of the tonsils;" since then had no throat trouble until the 6th day of March, when I found her suffering from an attack of diphtheria.

This yielded in about six days to the usual remedies of chl. potass., iron, salicylic acid, and quinine; as the throat cleared a croupy cough appeared, with considerable dyspnea. Attempted to combat these grave symptoms by means of a high temperature loaded with vapor, large doses tr. mur. iron, and direct inhalation of salicylic acid spray (gr. xx. to  $\bar{\zeta}$  i.) from an atomizer.

Gave also an expectorant mixture of syr. acct. sang. can. combined with syr. pruni. virg. every hour, with little or no apparent benefit. As the dyspnea grew hourly worse I had recourse to five gr. doses of Turpeth mineral, which produced prompt emesis, with temporary relief.

This treatment was continued, according to the exigencies of the case, from the 12th to the 15th, when, owing to her exhausted and partially asphyxiated condition, I relinquished all hope of benefit from medication, and resorted to tracheotomy. Assisted by Drs. Logue and McGuirk (Dr. L. having chloroformed the patient) I proceeded to open the trachea below the isthmus of the thyroid gland, with the happiest result.

All the loose diphtheritic matter was expelled immediately through the opening, and she breathed freely once more and partook of brandy, beef-tea, etc., kindly, though the stomach did not retain it.

A sinapism to the epigastrium checked the vomiting in a measure, and I then ordered the usual quinine powders to be administered every three hours, and an expectorant mixture of mur. ammonia, wild cherry and paregoric to allay the bronchial cough; also warm flaxseed meal poultices to be applied over the entire chest continually. All went well until 2 A.M. of the 19th, when she became thoroughly prostrated from cough, and efforts to expel an accumulated deposit which obstructed the tube.

With the assistance of a pigeon's feather and a forceps the obstruction was removed and a free administration of brandy caused a rally to her usual status.

From this time onward there were no untoward symptoms and her recovery was gradual and sure.

On the 4th day of April—three weeks less a day from the time of opening the trachea—she having recovered her voice, and respiration being normal, I removed the tube permanently. The opening, after removal of the tube, closed in about six hours.

500 CANAL STREET, N. Y.

By G. O. MORRISON-FISET, M.D.,

EXAMINING PHYSICIAN, DEPARTMENT OF THE OUT-DOOR POOR,  
BELLEVUE HOSPITAL, NEW YORK.

*Case IV.*—On December 26, 1875, at noon, I was called to a boy aged six years and four months. He had been taken sick six days before, first complaining of feeling chilly, and two days later of sore throat, with loss of appetite and sleep. When I saw the patient there was some difficulty of respiration present, accompanied by loud tracheal râles; the countenance was flushed and anxious; the tongue coated, and the pulse quick and full. An irregular white exudative patch was seen covering almost the entire surface of the left tonsil, and extended downwards. I accordingly diagnosed diphtheria. The lymphatic glands about the

lower jaw were not enlarged. Very little food had been taken by the patient for forty-eight hours, and vomiting had occurred frequently. The bowels were constipated, and there was retention of urine. Quinia was prescribed in five-grain doses, to be given every four hours, and the application to the diphtheritic patch, with a feather, of a solution of bromine (1 part to 40) of  $\text{Si}$ . to  $\text{Si}$  i. of water every morning and evening. A milk diet was ordered. Hot fomentations were ordered to be applied to the hypogastrium. At midnight I was again summoned to the patient. The dyspnea was now extreme; the countenance was greatly flushed, and the patient would roll in his bed from side to side, apparently in great distress. I administered eight grains of sulphate of zinc, which produced slight emesis and expectoration of mucus, but with little or no amelioration of the urgent symptoms present. The respiration was fast becoming more labored, and the pulse was getting feeble and more rapid. Dr. J. J. Reid was called in consultation, and tracheotomy was decided upon as the only chance left of saving the life of the patient. After obtaining the consent of the child's parents, chloroform was administered by Dr. Reid, and the operation of tracheotomy was performed by myself in the usual manner. After the introduction of the canula into the trachea the patient coughed a few times, expelling blood and mucus. Matters were brought to a crisis by the stoppage of all respiratory acts, and a few seconds later of cardiac pulsation. Artificial respiration was immediately resorted to and pushed on vigorously for at least twenty minutes. During this period the child would occasionally inspire, and the pulse could scarcely be felt at the wrist. The respiration and cardiac pulsation gradually became re-established, and we were rewarded at last, after twenty minutes of hard work, in keeping up artificial respiration. Stimulants and milk were freely administered, and the patient sank into a sound sleep which lasted for several hours. The same treatment was continued. The patient was seen five hours after the operation by myself, and was then sleeping. He was again seen at noon by Dr. Reid, and by myself in the evening. The patient's father was instructed to remove the inner canula frequently for cleansing purposes, which he carried out faithfully during the whole period that the tube remained *in situ*. Bronchitis developed after the operation, but was of a mild character and gave no trouble. The exudation seemed not to have extended below the larynx, as no exudative membrane was expelled at any time through the tube. The child made an excellent recovery, and the canula was removed on the twelfth day after the operation.

The points of interest connected with this case are: (1), the great advantage of the operation of tracheotomy in diphtheritic croup; (2), that the operation, to be useful, should not be postponed until the patient is cyanotic and pulseless; and (3) it shows the great necessity of performing artificial respiration, and persevering in it, though the case may be apparently a hopeless one.

The subject of the value of tracheotomy as a means of relief in diphtheritic croup has largely engaged the attention of the profession, and in this city, not many months ago, the subject was under discussion at a meeting of the Academy of Medicine. Many have questioned its value in this disease, but statistics are fast accumulating in favor of the operation. In reporting this case my view has been to add another successful one to the statistics bearing upon this important subject.

## Progress of Medical Science.

**CONDITION OF THE URINE IN ATROPHIC CHILDREN.**—MM. Parrot and Robin state that in the disease called arthrepsy of infants by the French, in other words atrophy dependent upon dyspepsia, they have constantly found a peculiar condition of the urine, which is only found in connection with other diseases when the latter are complicated with arthrepsy. In doubtful cases the diagnosis may be settled by this condition of the urine. It is always colored, varying from a pale lemon color to the deepest yellow; its smell is stale, nauseous, aromatic, and more or less strongly urinous; the quantity is always diminished, in the chronic form being often as low as 8-10 c.c., in the acute 5 c.c.; the specific gravity varies from 1009-1012.5. It is always cloudy and milky, except at the termination of very chronic cases, and at the setting-in of convalescence. The sediment which is almost always present contains different forms of casts, fatty elements with colored nuclei, uric acid, urates in crystals and powder, pigment, etc. The reaction is always acid, often exceedingly so. The quantity of urea is greatly increased; on an average it is 8.49 gr. per litre. The uric acid, coloring and extractive matters are also increased. Albumen is always present, though in variable quantities; sugar is also frequently present. The average quantity of the chlorides is from 3.9 to 3.28 gr., of the phosphates from 2.24 to 0.95 gr.—*Allg. Med. Central-Zeitung*, January 31, 1877.

**A CYST OF THE OVARY THAT RUPTURED INTO THE PERITONEUM DURING LABOR.**—On the evening of November 26, 1876, a woman was brought to the *Hôpital Cochin* in Paris, who had been in labor for three days. She was twenty-seven years of age, and was about eight and a half months pregnant. The bag of waters had broken three days before, and three attempts had been made to perform version before she had been sent to the hospital. No ergot had been given, according to all accounts. The early history of the case could not be obtained. On her admission to the hospital the left shoulder was found presenting in the second position, and two attempts were made to perform version, but the uterus was so firmly contracted that it was impossible to reach the feet or even the breech. Embryotomy was then performed by M. Polaillon. Before the operation the general condition was bad, the facies altered, the pulse rapid, and the abdomen excessively sensitive. On the morning of the 27th, the temperature was  $98\frac{1}{2}$ , the pulse small and rapid, the abdomen tympanitic, and there was bilious vomiting. The patient died at midnight.

**Autopsy.**—Stomach and intestines greatly distended with gas. Visceral and parietal peritoneum injected, red, but not covered with recent false membranes. The peritoneal cavity contained about  $1\frac{1}{2}$  litre of an opaque, sanguinolent fluid, in which the microscope revealed numerous pus globules and drops of fat. Kidneys, liver, lungs, and heart normal.

**Uterus.**—Cavity perfectly healthy. Its posterior face was covered with firm false membranes, connecting it with a tumor that filled Douglas's cul-de-sac. This tumor consisted of an empty sac, which contained only a blood-clot, and was almost large enough to contain the fist. Its walls were from  $\frac{1}{2}$  to  $\frac{3}{8}$  inches in thickness, the internal surface being mammillated. At its lower part, on the right side, there was a small perforation, through which a sound could be passed into the recto-uterine cul-de-sac. The tumor was connected with the uterus by the round ligament. Small

cysts as large as a hemp-seed, and containing a reddish fluid, were found in the thickness of its walls. The microscopical examination of the walls of the cyst showed that they were composed of an outer fibrous layer, and of an inner layer of embryonic tissue presenting all the characters of the tissue of the very vascular sarcomas, and M. Chambard, Malassez, and de Sinety believed it to be sarcomatous in nature.—*Le Progrès Médical*, 17 Février, 1877.

INDICATIONS FOR TREPHINING DRAWN FROM THE CEREBRAL LOCALIZATIONS.—At the meeting of the *Académie de Médecine* on January 9th, M. Lucas-Championnière read a paper on this subject. His attention had first been directed to it by a case in which he had successfully performed the operation of trepanning in 1874. The patient, after receiving an injury of the head, suffered from paralysis of a part of the muscles of the right arm and from aphasia. There was no wound, and the trephine had to be applied almost at hap-hazard; but still the operation succeeded perfectly. A fragment of the inner table was extracted with difficulty from the dura mater; the symptoms then gradually disappeared, and the patient recovered completely. M. Lucas-Championnière called attention to the fact that all the motor centres are grouped around the groove of Rolando; hence, when the position of the groove of Rolando is known, the situation of these centres will also be known. The summit of the groove is situated in men, on an average, 53 millimetres, and in women 48 millimetres behind the bregma. To find the bregma it is only necessary to remember that it is situated on the summit of a plane that passes through both auditory canals, when the head is held horizontally. A horizontal line seventy millimetres in length is then measured backwards from the external orbital apophysis, and from its extremity a perpendicular line thirty millimetres in height is raised. If now a line be drawn on the skin between the two points thus determined, we will have the *ligne Rolandique*, which will correspond with the groove of Rolando. Every time that M. Lucas-Championnière trepanned experimentally on this line, he came upon the groove of Rolando. It is necessary to apply the trephine about the middle of this line, when the symptoms are complicated; towards the summit if the lower limb be paralyzed, and rather towards its lower end when the upper limb is affected.—*Gazette des Hôpitaux*, 11 Janvier, 1877.

FISSURE OF THE ANUS IN INFANTS.—Dr. Mabbonix reports the case of a child of two months old, who for three weeks had suffered from constipation, with indications of great pain on passing the very hard motions. A fissure, with great contraction of the anus, was found on examination. Attention to the bowels and a salve of extract of rhatany effected a cure in six days.—*L'Union*, 1876.

PECULIAR ALTERATION OF THE NERVOUS CENTRES.—In a case of epithelioma with cylindrical cells starting from the ependyma of the fourth ventricle; in another case of solitary tubercle of the cerebellum and corpora quadrigemina; in a third case of solitary tubercle of the cavity of the fourth ventricle; and, finally, in a case of extensive sarcoma, situated above the corpus callosum, the substance of which was buried in equal proportions in the two hemispheres, and in another case of spina bifida, Dr. Vincenzo Brigidì (*L'Imparziale di Firenze*) has met with a peculiar alteration, consisting of numerous small round cavities excavated in the medullary substance, and filled with a dense, white, transparent substance,

which does not give the reaction of amylaceous or colloid matter, or mucin. The alteration is also distinguished by numerous characteristics from the vitreous degenerations of the French authors.

Dr. B. is inclined to regard this substance as liquefied myelin, which has collected between the nerve-fibres, in consequence of the rupture of the membrana limitans, and which later solidifies. He is not certain, however, that this is the true explanation of this hitherto undescribed appearance, and Ranvier, who has also examined the preparations, is likewise unable to offer a satisfactory explanation.—*Lo Sperimentale*, Feb., 1877.

BROWN-SÉQUARD ON LOCALIZATION IN BRAIN DISEASE.—In a discourse delivered recently in London Dr. Brown-Séquard analyzed and criticised the various views held by Broca, Sanders, Meynert, Fritsch, Hitzig, and others, as to the centre of disease in aphasia, and concluded that lesion of any part of the brain may produce this trouble. He therefore rejected the present theories by which aphasia is located in the third frontal convolution or in the island of Reil, and instanced a number of cases in which these so-called organs have been destroyed without affecting the speech, and others in which disease of the posterior lobe was the only apparent lesion discovered after death. He added, further, that great masses of the brain on either side might be destroyed without any marked alteration either in sensibility, in power of sight, or speech. His personal view is, that each function of the brain is carried on by special organs, but that these organs, instead of being composed of cells forming a cluster or mass in one part, are composed of scattered cells diffused in many parts of the brain, in communication, of course, one with the other by fibres, and forming a whole by this union of fibres, but still so diffused that a great many parts of the brain "contain the elements endowed with each of the various functions that we know to exist in the brain."—*Dublin Journal of Medical Science*, March, 1877.

CURABILITY OF ACUTE PHTHISIS (GALLOPING CONSUMPTION).—Dr. McCall Anderson, of Glasgow, in a recent clinical lecture, gave the histories of three cases of acute phthisis which terminated in recovery while under his care. All the cases followed exposure to cold and wet, and were characterized by a rapid course, with slight chills, high fever that rapidly assumed a typhoid type, rapid pulse and respiration, dry, coated tongue, costiveness, thirst, nausea, poor appetite, great weakness, with very rapid emaciation, frequent but not severe cough, mucous or rusty expectoration, delirium or stupidity and drowsiness, and profuse perspirations. The physical signs were slight dulness at the apices of the lungs, with abundant moist râles, and also dry râles over both lungs. The abdomen was not tympanitic, and there was no gurgling or iliac tenderness. The treatment consisted in iced cloths to the abdomen for half an hour every two hours, and in the internal administration of quinine gr. i., digitalis gr. i., and opium gr. ss., q. 4 h., with the view of reducing the fever; these remedies were used either alone or conjointly. The profuse sweats were checked by hypodermic injections of atropine gr.  $\frac{1}{100}$ , at night; in one of the cases the dose had to be increased to gr.  $\frac{1}{50}$ . The bowels were kept open by enemata or by oil. In order to keep up the strength of the patients, milk and soups, with brandy or champagne, were administered in small quantities at frequent intervals. In one case carbonate of ammonia was given.—*The Lancet*, March 24th and 31st.

# THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

## MISTAKES IN PRESCRIBING.

THE particulars of a case of accidental poisoning by corrosive sublimate have lately come to light, and may serve as a text for a passing comment on the much talked of relations between physicians and druggists, and the necessity of a proper understanding of mutual responsibilities. It appears that a physician wrote a prescription, of which the following is a copy:

"R. Hydrargyr. chloridi.....gr. vi.  
Pulv. opii.....gr. i.  
Put together in one paper."

The patient for whom it was intended presented it to a druggist, who gave her six grains of corrosive sublimate and one grain of opium. She took the medicine internally, in accordance with the directions of her physician, and it was only by the utmost promptness in the administration of any antidote that her life was saved. It appears to us that the blame for this accident rests equally between the physician and the compounder. The former maintains that he ordered calomel. He is certainly mistaken in this, as far as the name of the article goes, it was neither calomel nor corrosive sublimate, but an abbreviation of each, which gave an opportunity for much guessing, both calomel and corrosive sublimate are chlorides of mercury, but the former is known and written as the mild chloride (*hydrargyri chloridum mitis*) and the latter as the corrosive chloride (*hydrargyri chloridum corrosivum*). At best, the prescription was very carelessly written. Still this fact should not exonerate the dispenser from all blame. Knowing that he was dealing with a deadly poison, he should have made sure that the drug was not to be used internally before he allowed it to go out of his hands. If he presumed that the prescriber meant corrosive sublimate he should at least have written upon the paper "for external use." But it was such a small matter to inquire from the patient in a proper way as to how the medicine

was to be used that there is no excuse on the part of the clerk for not doing so. In the absence of any directions for the use of poisons, this rule should be absolute. The greater the liability for mistaking one drug for the other on account of similarity of name and appearance, the greater should be the precautions taken. This remark applies with peculiar force to calomel and corrosive sublimate. In writing for either there should never be any room for doubt as to the precise article indicated; that such doubt was created in this case shows negligence on the part of the prescriber. This want of forethought is the more apparent when we consider that there are terms to designate calomel which are universally recognized as distinctive. Even should there be an objection to the use of *calomelas*, the old-fashioned *hydrargyri sublimatus*, or the more recent term *hydrargyri subchloridum*, would never be questioned. On the other hand, the names *hydrargyri bichloridum*, or *hydrargyri chloridum corrosivum* would be equally explicit.

## THE DISTRIBUTION OF CASES FOR HOSPITALS.

THE distribution of hospitals throughout the city is perhaps everything that could be desired. Each of the large charities is situated far enough from the other to allow the city to be divided into hospital districts. This is perhaps a more fortunate circumstance than would at first appear. To those who may be the subjects of accident in different parts of this large city, the benefits arising from a reasonable proximity to a hospital are hardly to be calculated. In view of the fact that the longer the distance which a patient suffering from a severe accident has to be carried the less are his chances of recovery, no single hospital can possibly hope to monopolize such cases. It seems almost absurd, for the sake of sending sufferers to a particular hospital, that, *en route* thereto, one, if not two institutions which are willing to care for them, should be passed. And yet this is repeatedly done, not unfrequently at much risk to the patient and much positive and preventable suffering. It seems to us that the time has now come to make some new arrangements for cases of accident. We are informed that the police authorities are ready to take some action in the matter, provided the hospital authorities are willing to co-operate. Recognizing the difficulties and dangers of long transportation, they are anxious to entertain the proposition of dividing the city into suitable districts, provided the larger hospitals in such districts shall be willing to provide their own ambulances and have the same subject to call. This is certainly a proposition which deserves careful consideration and commends itself to all who are interested in the care of those who suffer from accidents, or who are suddenly stricken with disease. The police department is the proper one to take the matter in hand, and it is to be hoped that any efforts

which may be made in the direction of a proper distribution of cases will be promptly seconded by our hospital managers.

#### ENDOWMENT OF MEDICAL COLLEGES.

A RECENT number of the RECORD contained a letter signed ALUMNI, who made some pertinent inquiries as to a proposed *fund* which the Alumni of the College of Physicians and Surgeons of this city are endeavoring to raise, with the object of promoting superior medical education. The author of the article alludes to the fact that a sum of \$250,000 is sought for, and asks very properly, "Who is to have the custody of this fund and its special application?" He also says that "it does not give the information whether a special professorship is to be endowed, or all the present ones aided." He thinks, moreover, that it indicates "some concealed purpose," and desires to be enlightened on these matters. In answer to his inquiry, and for the benefit of those of the graduates who are interested in the work of the Association, it is proper to explain its present attitude by a reference to what it has done in the past. Incorporated on the 12th of May, 1873, it issued the same spring a circular endorsing the report of its Executive Committee, who recommended "the raising of a sum of money, not less than \$100,000 in amount, to be devoted to the following distinctive purposes: The endowment of a Chair of Pathological Anatomy, to be called the *Alumni Professorship of Pathological Anatomy*; the establishment of separate laboratories, where students may learn chemistry, physiology, and pathological anatomy experimentally, and where original researches may be carried on under the guidance of competent instructors; and the erection of one or two small recitation or lecture rooms, each capable of seating about thirty persons."

A good deal of energy was spent by different members of the Association in securing money and subscriptions, chiefly among the medical profession, and the fund thus started has slowly but gradually increased, until now it has reached a very respectable amount, though still very far from the sum first contemplated. During the present year it was thought advisable to issue another circular. A report was made which the Councillors and the Association adopted at their annual meeting, and to which the Trustees affixed their names. Though the amount now asked for is greater by \$150,000 than the original sum designated, it does not appear from the new circular that there is any necessary conflict between the two statements as to the purposes for which the money is to be used. The Alumni Association, it is to be understood, are not in a position to dictate as to what the disposal of the fund shall be, as is evidenced by the wording of their certificate of incorporation, which reads "that the objects for which the said corporation is formed are: the collection of funds by contribution and subscription, and the holding, investment, and application of the same for the establishment and endowment of professorships

and fellowships, the creation of prize funds, the establishment and equipment of laboratories, the erection and equipment of suitable buildings for the same, or the alteration and repair of buildings already erected, and for the purpose of buying, holding, and hiring or leasing property for any and such other purposes of medical and scientific investigation and instruction, in connection and co-operation with the Trustees of the 'College of Physicians and Surgeons in the city of New York,' as the said 'Association of the Alumni' of said college, in pursuance of its Constitution and By-laws, may direct." It may, therefore, be seen that whatever is done by the Alumni Association must be *in connection and co-operation* with the Trustees of the College of Physicians and Surgeons, a mutual relationship which is eminently proper for the two bodies to hold to one another.

Probably there is some diversity of opinion as to the way in which a fund of this kind should be expended, but there is no question that the leaning of the Association or its Councillors has been towards more thorough and extended instruction in Pathological Anatomy, and the foundation of a chair in this branch was earnestly hoped for. This fact is emphasized by the Secretary of the Association in his recent reply to Alumni. The fund for this purpose has been known as the "Pathological" or "Laboratory" fund, and amounts to something over \$15,000. The exact method of employing it has been earnestly discussed though without reaching any definite conclusion; any action contemplated by the Alumni Association must, it is to be remembered, be done *in connection and co-operation* with the Trustees of the College of Physicians and Surgeons, whose consent is therefore to be obtained. At the same time the Association has a right to, and would doubtless require, guaranties for the proper use of its money. At a recent meeting a resolution was passed by which a committee was to be appointed to confer with the Faculty of the College of Physicians and Surgeons, with a view of reaching some understanding, that prospective action might be intelligent and in unison. There is no doubt that the present state of uncertainty which exists as to the employment of the fund greatly embarrasses the work of the Association, and has prevented many of those who have the welfare of the college most at heart from giving it aid. We therefore await the report of the committee with some interest, and anxiously hope that the friends of the college may be informed at the earliest practicable moment of the plans which these two bodies jointly recommend. Decisive action is required now, that the enterprise in which the Alumni Association has embarked may not fail through lack of definiteness in its stated purpose.

#### MARINE HOSPITAL SERVICE.

SINCE 1873 the Marine Hospital Service has required candidates to pass a good practical examination as to professional qualifications, and the good results of

ained show the importance of the change. Formerly no examination was deemed necessary, and the result was that, although there were good men in the service, still persons without proper qualifications or professional skill were constantly creeping in, much to the detriment of the service. The last report contains many interesting articles, among which those on yellow fever, malarial fever, and syphilis, deserve special notice. The maps and tables are elaborate, and evince a patient and conscientious study of the subjects.

## Reviews and Notices of Books.

TRANSACTIONS OF THE AMERICAN GYNECOLOGICAL SOCIETY, Vol. I., for the year 1876. Boston: H. O. Houghton & Co. 1877. Svo, pp. 396.

ON June last a number of gynecologists from various parts of the United States, in answer to a call issued during the previous month, assembled at the Academy of Medicine, and founded the American Gynecological Society. On the following September, and in this city, the first meeting of this Association was held, a detailed account of which forms the contents of the volume before us. With a membership thoroughly representative, and with an interest thoroughly cosmopolitan, its success was almost a foregone conclusion. Our readers have been presented already with an abstract of the proceedings of the first meeting, and will agree with us in a high estimate of their worth to practical gynecology. In the present volume all the papers which were read during the session are published in detail. As contributions to advanced gynecology they exceed in value anything which we have ever before seen collected in any one volume. Without exception, every paper has an interest and value attached to it which is intrinsic and which reflects the best efforts of the respective authors. Each seemed actuated by a single purpose, and each has succeeded in the effort to widen the sphere of observation in one of the most important departments of the healing art. The number and variety of the papers read quite forbids the possibility of a critical review of them in the space which is allotted to us, but we can give some idea of the scope of the volume by reference to them by title. The first score of pages is occupied by the history of the inauguration of the Society, its constitution and by-laws, list of officers and minutes of the first annual meeting in abstract. Then follows the annual address of the President, Dr. Fordyce Barker, which is full of valuable suggestions in regard to the management of discussions, and to all other matters pertaining to the success of scientific meetings. We wish it could be placed in the hands of every president of a medical society in the country, or we are convinced that a heed of its precepts would culminate in the "expression of careful study, deliberate judgment, and mature experience." But this is merely *en passant*. The following are the papers in the order of their appearance in the volume:

- I. Etiology of Uterine Flexures, with the proper mode of treatment indicated. By Thomas Addison Emmet, New York.
- II. Cicatrices of the Cervix Uteri and Vagina. By Alexander J. C. Skene, M.D., New York.
- III. Extirpation of the Functionally Active Ovaries or the Remedy of Otherwise Incurable Diseases. By Robert Battey, Rome, Ga.

IV. *Viburnum Prunifolium* (Black Haw); its uses in the treatment of women. By Edward W. Jenks, M.D., Detroit, Mich.

V. An Illustration of *Xenomelia*. By Theophilus Parvin, M.D., Indianapolis, Indiana.

VI. Relations of General Pregnancy to General Pathology. By Robert Barnes, M.D., London, Eng.

VII. The Spontaneous and Artificial Destruction and Expulsion of Fibrous Tumors of the Uterus. By W. H. Byford, Chicago, Ill.

VIII. Case of Abdominal Pregnancy Treated by Laparotomy. By T. Gaillard Thomas, M.D., New York.

IX. Pneumatic Self-Replacement in Dislocations of the Gravid and Non-Gravid Uterus. By Henry F. Campbell, M.D., Augusta, Ga.

X. Hydrate of Chloral in Obstetrical Practice. By W. L. Richardson, M.D., Boston, Mass.

XI. Labor Complicated with Uterine Fibroids and Placenta Prævia. By James R. Chadwick, M.D., Boston, Mass.

XII. Latent Gonorrhœa, with Regard to its Influence on Fertility in Women. By Emil Noeggerath, M.D., New York.

XIII. Death from Urinemia in Certain Cases of Malignant Disease of the Uterus. By Alfred Wiltshire, M.D., London, England.

XIV. Clinical Memoir on Some of the Genital Lesions of Childbirth. By William Goodell, M.D., Philadelphia, Pa.

XV. Hermaphroditism. By Lawson Tait, F.R.C.S., Birmingham, England.

XVI. Cases of Cystic Tumors of the Abdomen and Pelvis. By Geo. H. Bixby, M.D., Boston, Mass.

XVII. Case of Solid Uterus Bipartitus; both ovaries removed for the relief of epileptic seizures ascribed to ovarian irritation. By E. Randolph Peaslee, M.D., New York.

XVIII. The Origin and History of Calculi Found in the Bladder after the Cure of Vesico-Vaginal Fistula by Operation. By Henry F. Campbell, Augusta, Ga.

XIX. Rare Forms of Umbilical Hernia in Fœtus. By James R. Chadwick, M.D., Boston, Mass.

XIX. In Memoriam Gustav Simon. By Paul F. Mundé, M.D., New York.

The work is elegantly printed, neatly and tastefully bound.

BLAPS MORTISAGRA AS A HUMAN PARASITE.—The larva of this insect, known as the churchyard beetle, was found in the motions of a child eleven years of age, by Mr. Horne, and sent to Dr. T. Spencer Cobbold. The child had been brought up on boiled cow's milk, but before the discovery of the insect it had suffered from diarrhœa, for which hydrarg. c. cretâ and rhubarb were prescribed, which appear, according to Dr. C., to have acted anthelmintically. The evidence is not regarded as particularly strong in itself, but in accordance with what has previously been published, as, for example, in the case of Mary Riordan, who passed upwards of 1,200 larvae, and several perfect insects of this species. Pickells, and Thompson, and Patterson, and Bateman have published other similar cases. It is not known how the maggot entered the child in this instance, though with Mary Riordan it was comparatively easy to explain the matter. She was in the daily habit of drinking water mixed with clay taken from the graves of two Catholic priests, and eating large pieces of chalk.

Some absurd or superstitious notions are usually at the bottom of the whole matter. The insect is very intolerant of the light, and loves to bury itself in the ground.

## Correspondence.

### A METHOD OF MEASURING THE LOWER EXTREMITIES.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—By the ordinary method of obtaining the comparative length of the lower extremities, it is difficult to get exact results. Even when every precaution is taken to guard against the obliquity of the pelvis (which is the chief source of error), an eighth or even a quarter of an inch difference may escape detection. Such at least is the case when measurement is made between the spinous process of the ilium and the malleolus on each side. Neither of these presents a point, but a surface which in persons well-clothed in flesh occupies considerable area. When measurement is made from the umbilicus or episternal notch to the middle of the sole of each foot (Sayre's method, I believe), this difficulty is, perhaps, done away with. I have, however, for several years past adopted another plan, which is, I think, more convenient, and by which the liabilities to error (when a tape-line alone is used) are reduced to a minimum. The plan is this: The patient, lying on the floor or a table (a soft mattress will confuse any measurement), the parallelism of the iliac spines and the proper extension of the limbs being looked to, a point is taken on the umbilicus, and marked with ink, if necessary. Commencing at this point, the tape is carried in turn *around the sole of each foot and back again to the point of departure*. The difference between the two measurements thus obtained represents *twice* the amount of difference which exists in the length of the limbs. For instance, if the measurement thus obtained when the tape is carried around the right foot is fifty-four inches, and when carried around the left foot it is fifty-five inches, the difference in the length of the limb is *half an inch*.

Of course care must be taken to carry the tape around corresponding portions of each foot, and in the same direction—from within, outward, or *vice versa*—on both sides. A great amount of swelling in the foot may also occasion error, but not to the extent it might be imagined. I think the method described will be found convenient and useful, either when employed alone or to verify results obtained by other plans. It has the advantage of indicating small differences, as these are multiplied.

RICHARD O. COWLING, M.D.

LOUISVILLE, KY.

### THE TONIC AND THE SPECIFIC ACTION OF MERCURY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—I believe you always allow a few lines for the correction of an error, and a very serious one appeared in your issue of May 5th, page 282. Your reviewer of the "Tonic Treatment of Syphilis" there says, "The gist of this book is, that mercury is a tonic in syphilis, hence it must be given."

Such a doctrine is absurd, and I cannot accept the responsibility of fathering it. It is not even remotely hinted at in the book criticised. A portion of one of the chapters indeed is solely devoted to proving the contrary, namely, that the iodides, while more tonic than mercury, have no curative action over the disease.

The specific action of mercury is treated as a matter of universal recognition (pp. 12, 26, 27), and no new theory is advocated. The book is simply this:

a rational treatment is studied and *proved* to be not only not injurious, but (accidentally) tonic to the patient, and therefore it is recommended to the profession in detail on a basis of fact.

An effort is also made in the book to help sweep away a nearly universal prejudice against a much abused drug.

The author of the "tonic treatment" has a theory which fully explains the "modus operandi" of the tonic (not of the specific) action of mercury, which your reviewer demands; but he has not published this theory, preferring to confine himself to facts.

Two errors of fact made by your reviewer require correction; his statements (1) that mercury has been long and generally *recognized* as tonic; (2) that Fourrier founded the continuous mercurial treatment of syphilis—since it is notorious that this eminent gentleman has founded a treatment the very essence of which consists in intervals of intermission between interrupted mercurial courses.

Very respectfully,

E. L. KEYES, M.D.

20 MADISON AVE.

### A QUESTION OF PRIORITY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In the RECORD for April 21st, there seems to be a credit given to Dr. S. W. Gross for a very ingenious and valuable device for securing extension in fractures below the knee. The credit properly belongs to Dr. H. F. Montgomery, of Rochester, N. Y., who described the device and its application in the April (1871) No. of *Am. Jour. Med. Sciences*.

Respectfully yours,

M. A. McCLELLAND.

KNOXVILLE, ILL., April 23, 1877.

### ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from April 29 to May 5, 1877.*

#### PROMOTIONS.

SLOAN, WM. J., Lieut.-Colonel. To be Colonel and Surgeon, *vice* McCormick, deceased.

PERIN, G., Major. To be Lieut.-Colonel and Surgeon, *vice* Sloan, promoted.

HUNTINGTON, D. L., Captain and Asst. Surgeon. To be Major and Surgeon, *vice* Perin, promoted.

PHILLIPS, H. J., Asst. Surgeon. Granted leave of absence for six months on surgeon's certificate of disability, with permission to go beyond sea. S. O. 91, A. G. O., April 28, 1877.

HEIZMANN, C. L., Asst. Surgeon. Assigned to temporary duty at Fort Wadsworth, N. Y. Harbor. S. O. 96, Mid. Div. Atlantic, May 2, 1877.

GIRARD, A. C., Asst. Surgeon. Assigned to duty at Fort Randall, D. T. S. O. 54, Dept. of Dakota May 1, 1877.

THE HOSPITAL GAZETTE is a new monthly medical journal published in this city. It is under the editorial management of Dr. Frederick A. Lyons, and is published by Rutledge & Co. The first number, which is for the month of April, presents a very creditable appearance and is filled with varied and interesting material. We gladly welcome it to our exchange list and wish it success.

## New Instruments.

### NEW HYPODERMIC SYRINGE.

By S. PETERS, M.D., AND F. S. PETERS, M.D.,

CORHES, N. Y.

The hypodermic syringe as now constructed has some faults which need correction. If remedies for disease, antidotes for poisons, even nutrition in failure of the vital powers, in certain cases are to be often preferably introduced under the skin, certainly the instrument for accomplishing these important things should be relieved of as many defects as possible. Two or three of these which are certainly important ones we have endeavored to remedy. They are: First, the drying of the piston. Secondly, the necessity of carrying a vial for the solution; and thirdly, the loss of time in drawing the solution into the syringe preparatory to performing the injection. These several faults, as will be apparent, are overcome at once by a simple arrangement for carrying the medicated solution in the barrel of the syringe, above the piston, and for transferring at pleasure any number of minims for immediate use below the piston ready for injecting. Thus the piston is always kept moist, the solution is always secure in the syringe itself, and further, it is ready for use at a moment's notice. The peculiar construction of our syringe, by which the above is conveniently effected, is described briefly as follows: In the centre of the piston is fixed a small tube extending slightly above the upper surface; within this rotates another tube, which is fixed to the piston-rod, which as usual passes up through the cap of the syringe. In each of these tubes above the piston is made a small opening on one side. These openings when opposite form a communication between the upper and lower chambers. The operation is this: Turn the piston-

rod so that the openings in the tubes are opposite, that is till the communication is closed, then draw the barrel of the syringe full of the medicated solution, place the finger over the point at the needle end, open the communication, and press home the piston, thus the solution is transferred to the upper chamber, where it may be carried for any length of time, evaporation being prevented below by closing the communication, and above by the packing in the cap of the syringe. When an injection is required, the needle being fixed upon the point of the syringe, the communication opened, the piston is drawn up till the desired number of minims is displaced to the lower chamber, then close the communication, insert the needle, press home the piston, and the operation is completed. It is very evident that this syringe can be used any ordinary syringe, even while the upper chamber filled, or rather nearly filled, with the medicated solution, because when the communication through the piston is closed, it is in all respects like any other, hence another advantage over others.

Messrs. Geo. Tiemann & Co., of New York City, have undertaken the manufacture of this instrument.

### A MODIFICATION OF SIEGLE'S OTOSCOPE.

By EDWARD T. ELY, M.D.,

NEW YORK.

The modification of Siegle's otoscope herewith presented is believed by the writer to be an improvement upon the ordinary forms of that instrument. It is

much more agreeable for the surgeon than the procedure of making suction with his own mouth—especially among dispensary patients; and it abolishes the need of an assistant, which exists when the stomach-pump attachment, suggested by Dr. Howard Pinkney, is used. Moreover, it gives the operator more complete command of the force which he employs, so that he can make this as violent or as gentle as he chooses.

The air is exhausted through the pneumatic speculum by a small syringe similar to those attached to aspirators. The body of the syringe is only three inches long and five-eighths of an inch in diameter; but it seems to be perfectly efficient. The piston is easily worked with the thumb of the disengaged hand, while the action of the drum-head is watched under illumination from the forehead-mirror. The valves of the syringe being so arranged that the air can escape only backwards, as many movements of the piston as desired can be made without removing the speculum from the ear. The rubber tubing should be very flaccid, as it will then collapse the instant a vacuum is formed, thus giving a trustworthy sign of that fact to the surgeon. The usual precautions about having the speculum fit the auditory canal accurately should of course be observed.

Anything which renders the diagnostic and therapeutic uses of Siegle's otoscope so simple and agreeable would seem to be of advantage. A busy surgeon often omits some of his possible appliances for diagnosis and treatment simply because their use is attended with a little inconvenience.

The instrument described above can be procured of Reynolds & Co.

HEALTH BOARD OF MINNESOTA.—The fifth annual report of the State Board of Health of Minnesota contains much valuable information for the student, the practitioner, and the statistician. Although there has been less epidemic prevalence of disease, less sickness, and less mortality than for several preceding years, the reports on "Infant Mortality," small-pox, and the means for its prevention, scarlet fever, and other eruptive diseases, etc., are very thorough. The inspection of the public institutions form an important feature of the report, and should be emulated by our Metropolitan and State Boards of Health. The essay on the heating and ventilation of schools, etc., especially deserves a careful perusal, the author, Dr. Charles N. Hewitt, showing a familiarity with the subject only equalled by the originality of his views.

## Medical Items and News.

CONTAGIOUS DISEASES.—Comparative statement of cases of Contagious Disease reported to the Sanitary Bureau, Health Department, for the two weeks ending May 5, 1877.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-Spinal Meningitis.	Measles.	Diphtheria.	Small-pox.
April 28.....	0	7	85	4	26	40	5
May 5.....	0	5	110	1	26	33	3

INTERNATIONAL EXPOSITION OF 1878.—Among the sections which will be contained in the International Exposition of 1878, one of the most interesting will be that of the anthropological sciences. We learn that the *Société d'Anthropologie*, of Paris, has taken the initial steps for a special exhibition of the anthropological sciences, comprising anthropology, properly so-called, and craniology; ethnography, especially that of France and Europe; paleo-ethnology or prehistoric archeology; demography or compared statistics; linguistic geography. It has appointed for this purpose a commission, the President of which is M. de Quatrefages, Member of the Institute; the Vice-Presidents are M. Henri Martin, Senator and Member of the Institute, and Dr. Paul Broca, and the Secretaries are M. Gabriel de Mortillet and Dr. Paul Topinard.

M. le Sénateur Krantz, Commissary-General of the International Exposition, has placed at the command of the commission the vast space comprised in the galleries which surround the central hemicycle of the Palais du Trocadero. The commission makes a warm appeal for assistance to all those, either in France or in other countries, who are interested in the advancement of the anthropological sciences. It is the desire of the Society to present a complete inventory of the present state of the sciences.

The objects to be exhibited will be placed under the following categories: 1st, skulls and bones, mummies, preparations illustrating the comparative anatomy of the human race; 2d, instruments, systems of education; 3d, prehistoric and ethnographical collections; 4th, photographs, paintings and designs, sculptures and models; 5th, geographical charts and tables having reference to ethnology, prehistoric archeology, language, demography, and medical geography; 6th, books, journals, brochures.

ACADEMY OF MEDICINE.—At a stated meeting of the New York Academy of Medicine, held May 3, 1877, Drs. E. C. Harwood, E. J. Birmingham, and A. H. Smith were elected Resident Fellows.
